Abstract

	Introduction: In traditional pharmacokinetic (PK) bioequivalence analysis, two one-sided	2
	tests (TOST) are conducted on the area under the concentration-time curve and the max-	3
	imal concentration derived using a non-compartmental approach. When rich sampling is	4
	unfeasible, a model-based (MB) approach, using nonlinear mixed effect models (NLMEM)	5
	is possible. However, MB-TOST using asymptotic standard errors (SE) presents increased	6
	type I error when asymptotic conditions do not hold.	7
	Methods : In this work, we propose three alternative calculations of the SE based on	8
	i) an adaptation to NLMEM of the correction proposed by Gallant, ii) the <i>a posteriori</i>	9
	distribution of the treatment coefficient using the Hamiltonian Monte Carlo algorithm,	10
	and iii) parametric random effects and residual errors bootstrap. We evaluate these ap-	11
	proaches by simulations, for two-arms parallel and two-periods two-sequences cross-over	12
	design with rich $(n=10)$ and sparse $(n=3)$ sampling under the null and the alternative	13
	hypotheses, with MB-TOST.	14
	Results: All new approaches correct for the inflation of MB-TOST type I error in PK	15
	studies with sparse designs. The approach based on the $a \ posteriori$ distribution appears	16
	to be the best compromise between controlled type I errors and computing times.	17
	Conclusion: MB-TOST using non-asymptotic SE controls type I error rate better than	18
	when using asymptotic SE estimates for bioequivalence on PK studies with sparse sam-	19
	pling.	20
Kevv	words and Phrases: pharmacokinetics, bioequivalence, nonlinear mixed effects model, two	21
v	sided tests, non-asymptotic standard error	22

1 Introduction

23

Bioequivalence studies are routinely conducted for the development of generics or the adoption 24 of new formulations of existing drug. According to current guidelines by regulation authorities 25 both in the US and the EU [1, 2], bioequivalence between a reference (R) and a test (T) product 26 is to be assessed based on the comparison of their respective area under the time-concentration 27 curves (AUC) and maximal concentrations (C_{max}). The presently recommended statistical 28 approach is to claim bioequivalence if the boundaries of the 90%-confidence intervals around 29 the ratios of AUC and C_{max} geometric means of both groups do fall between 0.8 and 1.25. This 30 is equivalent to performing a two one-sided tests (TOST) proposed by Schuirmann [3]. 31

Traditionally, individual estimates of AUC are obtained using non-compartmental analysis 32 (NCA-TOST). Based on few hypotheses, NCA requires dense pharmacokinetic (PK) sampling. 33 In especially fragile populations (e.g., children or patients), or for specific indications (e.g., 34 ophthalmic drugs), it may be challenging and/or unethical to collect such dense sampling. 35 Therefore to assess the PK bioequivalence of two ophthalmic drugs on a study with only one-36 time point per subject, Shen et al. proposed a non parametric bootstrap NCA-based TOST[4]. 37 A population PK model-based (MB) approach is another appealing alternative when dense 38 PK samplings cannot be obtained, as it lowers the individual sampling burden by borrowing 39 information across patients. . 40

In 2010, Dubois et al. compared the type I error and power of the NCA-TOST to a TOST 41 based on individual empirical Bayes estimates (EBE) from a nonlinear mixed effect model 42 (NLMEM)[5]. They found that, when the shrinkage is above 20%, using NCA TOST leads to a 43 modestly increased type I error whereas using TOST on EBE leads to a more severe type I error 44 inflation. They suggested to perform a TOST directly on the treatment effect estimate from 45 the NLMEM (MB-TOST) using the asymptotic standard error (SE). In 2011, they evaluated 46 the MB-TOST using Wald test and likelihood ratio test and found an inflation of the type I 47 error when asymptotic conditions are not met, which is the underlying condition for applying 48 Delta method, that is, for very sparse sample (number of samples per subject is limited), or 49 small sample size (number of subjects is small), or high variability. Further, they associated this 50 inflation to an under-estimation of the SE of the treatment effect coefficient, due to the use of 51 an asymptotic approximation, i.e., the observed Fisher Information matrix (FIM). So the MB-52 TOST in its current form does not meet the standards of regulatory agencies for confirmatory 53 tests. 54

Therefore, the primary objective of this work is to propose alternative approaches to calculate ⁵⁵ the SE, guarantying for the MB-TOST a nominal type I error on sparse sampling PK studies. ⁵⁶ First, we adapted the correction based on the work by Gallant [6] which Bertrand et al. extended ⁵⁷ to Wald tests in NLMEM, in case of small sample size studies [7]. Second, we proposed to sample ⁵⁸ in the *a posteriori* distribution of population parameters obtained by Hamiltonian Monte-Carlo using Stan [8], as proposed by Ueckert et al. [9]. Third, we used parametric bootstrap, which was shown to perform better than case bootstrap and non parametric residual bootstrap when the true model and variance distribution are used [10].

We evaluated MB-TOST using these approaches by clinical trial simulations with parallel and cross-over designs, with rich and sparse samplings.

Although the TOST is very efficient in most cases, it has proven to be too conservative on 66 drugs with high variability [11]. Therefore, Möllenhoff et al. proposed a bioequivalence optimal 67 test (BOT) as an alternative to the TOST for bioequivalence assessment in such situations 68 [12]. They adapted this test to the MB approach (MB-BOT), and showed that this method 69 appears to have closer type I errors to the conventionally accepted significance level of 0.05 than 70 the MB-TOST for drugs with high variability. However, they also noticed an inflation of the 71 type I errors on sparse designs, showing that the SE-computation method is also an issue with 72 MB-BOT. In supplementary material 2, we evaluate MB-BOT along with the proposed SE-73 calculation approaches. Then, we further study the conjoint influence of design and variability 74 on the SE of the treatment effect on AUC and C_{max} , and thus on type I error and power of 75 MB tests. Thereafter, we determine a threshold on the SE above which MB-BOT should be 76 recommended over MB-TOST. 77

In Section 2, we introduce the NLMEM, the MB-TOST as well as the different SE calculations. ⁷⁸ In Section 3, we present the clinical trial simulations performed to evaluate the approaches. In ⁷⁹ Section 4, we present the results, i.e., type I error and power of the different approaches and ⁸⁰ finally in Section 5, we discuss the conclusions and perspectives of this work. ⁸¹

2 Methods

2.1 Nonlinear mixed effects models

The concentration $y_{i,j,k}$ of subject i (i = 1, ..., N), at period k (k = 1, 2), at sampling time $t_{i,j,k}$ $(j = 1, ..., n_i)$ is described by a nonlinear function f depending on the vector of individual parameters $\phi_{i,k}$ of subject i at period k

$$y_{i,j,k} = f(t_{i,j,k}, \phi_{i,k}) + g(t_{i,j,k}, \phi_{i,k})\varepsilon_{i,j,k}.$$
(1)

The l^{th} individual parameter $\phi_{i,k,l}$ (l = (1, ..., p)) is defined by the following equation, where p so the number of PK parameters set p so that p is the number of PK parameters set p so that p is the number of PK parameter p so that p is the number of PK parameter p so that p is the number of PK parameter p so that p is the number of PK parameter p so that p is the number of PK parameter p so that p is the number of PK parameter p so that p is the number of p is in p is the num

$$\log(\phi_{i,k,l}) = \log(\lambda_l) + \beta_l^{Tr} Tr_{i,k} + \beta_l^P P_k + \beta_l^S S_i + \eta_{i,l} + \kappa_{i,k,l},$$
(2)

83

82

with λ_l the l^{th} element of the vector of fixed effects for the covariate reference class. $Tr_{i,k}$, P_k , ⁸⁹ S_i are known vectors of, respectively, the treatment, the period, and the sequence covariates. ⁹⁰ β_l^{Tr} , β_l^P , and β_l^S are the l^{th} elements of the vectors of coefficients of the treatment, the period, ⁹¹ and the sequence effects for the individual parameter. ⁹²

 $\eta_{i,l}$ is the l^{th} element of the vector η_i of random effects of subject *i* capturing the between-subject variability (BSV). $\kappa_{i,k,l}$ is the l^{th} element of the vector $\kappa_{i,k}$ of random effects of subject *i* at period *k* capturing the within-subject variability (WSV). η_i and $\kappa_{i,k}$ are assumed independent and normally distributed with zero mean and covariance matrix, respectively Ω and Γ , both of size $p \times p$. We define ω_l^2 the between-subject variance of the l^{th} parameter, and γ_l^2 the within-subject variance of the l^{th} parameter.

The residual errors $\varepsilon_{i,j,k}$ are supposed independent and identically distributed according to a normal centered distribution with variance 1. The error model can be additive $g(t_{i,j,k}, \phi_{i,k}) = a$, proportionnal $g(t_{i,j,k}, \phi_{i,k}) = b \times f(t_{i,j,k}, \phi_{i,k})$, i.e., additive on log-concentrations, or combined $g(t_{i,j,k}, \phi_{i,k}) = a + b \times f(t_{i,j,k}, \phi_{i,k})$.

We denote by $\theta = (\lambda, \beta^{Tr}, \beta^P, \beta^S, \Omega, \Gamma, a, b)$ the vector of all parameters of the model, and by $\widehat{VAR}(\hat{\theta})$ the estimation variance-covariance matrix, derived as the inverse of the observed FIM. 105

Here, bioequivalence is assessed on β_{SP}^{Tr} the coefficient of the treatment on the secondary PK parameters of interest SP={AUC or C_{max} }. For each secondary parameter, β_{SP}^{Tr} is a function of λ and β^{Tr} and its SE is derived from $\widehat{VAR}(\hat{\theta})$.

2.2 Model-based TOST

The MB-TOST global null hypothesis is expressed as $H_0: \beta_{SP}^{Tr} \leq -\delta$ or $\beta_{SP}^{Tr} \geq \delta$ and can be 111 divided in two sub-hypotheses: $H_{0,-\delta}: \beta_{SP}^{Tr} \leq -\delta$ and $H_{0,\delta}: \beta_{SP}^{Tr} \geq \delta$. 112 Therefore, the MB TOST consists in two Wold statistics: $W_{0,-\delta}: \beta_{SP}^{Tr} \geq \delta$.

Therefore, the MB-TOST consists in two Wald statistics: $W_{-\delta} = (\hat{\beta}_{SP}^{Tr} + \delta)/SE(\beta_{SP}^{Tr})$ and 113 $W_{\delta} = (\hat{\beta}_{SP}^{Tr} - \delta)/SE(\beta_{SP}^{Tr})$, respectively testing $H_{0,-\delta}$ and $H_{0,\delta}$, with $SE(\beta_{SP}^{Tr})$ the standard error 114 on the estimation of a secondary parameter $SP = AUC, C_{max}$. In an asymptotic setting, $W_{-\delta}$ 115 and W_{δ} can be assumed to follow a Gaussian distribution under $H_{0,-\delta}$ and $H_{0,\delta}$, respectively. 116 So, the global null hypothesis H_0 is rejected with type I error α if $W_{-\delta} \geq z_{1-\alpha}$ and $W_{\delta} \leq -z_{1-\alpha}$ 117 where $z_{1-\alpha}$ is the $(1-\alpha)$ -quantile of the standard normal distribution. 118 Alternatively, one can compute the $(1-2\alpha)$ confidence interval (CI) of β_{SP}^{Tr} and reject the global 119 null hypothesis if it is included in the interval $[-\delta; \delta]$. 120

For MB-TOST, the asymptotic approach (Asympt.) consists in using $\widehat{VAR}(\hat{\theta})$, $\hat{\lambda}$, and $\hat{\beta}^{\hat{T}r}$ 122 for deriving the SE of the secondary parameters (SE(β_{SP}^{Tr})) with the delta method [13]. The 123 analytical formulas are shown in detail in Appendix A of Dubois et al. [14]. 124

110

121

103

2.3 New approaches for standard error (SE) calculations

Gallant. This method consists in multiplying the asymptotic SE by a factor equal to $\sqrt{\frac{n_P \times N}{df_G}}$ using the number of periods, N is the number of subjects, and $df_G = n_P \times N - p$. For MB-TOST, the reference distribution is the Student distribution.

Sampling in the *a posteriori* distribution (Post). This method consists in sampling in ¹²⁹ the *a posteriori* distribution of β^{Tr} . The *a posteriori* distribution is obtained using Hamiltonian ¹³⁰ Monte-Carlo (HMC). We assigned default priors to the fixed effects $(\lambda, \beta^{Tr}, \beta^P, \beta^S)$ and noninformative half Cauchy priors to variance terms. The HMC chain was initialized at $\hat{\theta}$, $\hat{\eta}_i$, and ¹³² $\hat{\kappa}_{i,k}$ from the NLMEM analysis using the SAEM algorithm. For each resulting sample of λ ¹³³ and β^{Tr} , we derive a corresponding β^{Tr}_{SP} and the standard deviation of this series is the *Post* ¹³⁴ $SE(\beta^{Tr}_{SP})$.

Parametric random effect and residual bootstrap (Boot). This method consists in ¹³⁶ simulating b = 1, ..., B datasets with the original bioequivalence study design. The subject ¹³⁷ random effects and residuals are issued from distributions with means and variances equal to ¹³⁸ the estimated population parameters from the original bioequivalence study NLMEM analysis. ¹³⁹ Then, the B datasets are fitted with a NLMEM and B replicates of $\beta_{SP_b}^{\hat{T}r}$ are calculated as ¹⁴⁰ functions of the $\hat{\lambda}_b$ and $\beta_b^{\hat{T}r}$ estimates. The standard deviation of this series is the Boot $SE(\beta_{SP}^{Tr})$. ¹⁴¹

3 Simulation Study

3.1 Pharmacokinetic model

We used the PK model from Dubois et al. [14], which describes concentrations of the antiasthmatic drug theophylline, for both reference and test group, with a one-compartment distribution (apparent volume, V/F) and first-order absorption (absorption rate, Ka) and elimination (apparent clearance, CL/F). We fixed the dose to D = 4 mg for all subjects. For the reference treatment, we considered $\lambda_{Ka} = 1.50$ /h, $\lambda_{CL/F} = 40.00$ mL/h, and $\lambda_{V/F} = 0.50$ L. 148

We considered a combined error model with a=0.1 mg/L and b=10\%, corresponding to a low 149 residual variability. 150

The bioequivalence threshold δ was set at $log(1.25) \approx 0.22$ as recommended by the guidelines [15].

153

142

143

3.2 Treatment effect

We simulated under one null hypothesis $H_{0,\log(0.8)}$, i.e., $\log(AUC^T/AUC^R) = \log(C_{max}^T/C_{max}^R) = 155$ log(0.8), where AUC^T/AUC^R and C_{max}^T/C_{max}^R are the ratios of geometric means of T to R formulations of AUC and C_{max} respectively [16]. The corresponding treatment effect coefficients 157 modifying both CL/F and V/F are $\beta_V^{Tr} = \beta_{CL}^{Tr} = \log(1.25)$.

We also simulated under one alternative hypothesis by setting $\beta_{CL}^{Tr} = \beta_V^{Tr} = \log(1)$, which ¹⁵⁹ corresponds to $\beta_{AUC}^{Tr} = \beta_{C_{max}}^{Tr} = \log(1) = 0.$ ¹⁶⁰

3.3 Study Design

We simulated two-arms parallel and 2-periods 2-sequences cross-over designs (as in [14]). For 163 both trials, we simulated a rich and a sparse design, both with N=40 subjects. For the rich 164 design, there were n=10 samples per subject, taken at 0.25, 0.5, 1, 2, 3.5, 5, 7, 9, 12, 24 hours 165 after dosing. For the sparse design, we simulated n=3 samples per subject, taken at 0.25, 3.35 166 and 24 hours after dosing. We considered the same sparse design as in [14, 17]. The sampling 167 times for this design were chosen by maximization of the determinant of the Fisher information 168 matrix for an individual nonlinear model using the fixed effect values. This was done using the 169 PFIM software [18] with a sampling window from 15 min to 24 hours. 170

We first simulated a parallel design (Figure 1), where N/2 subjects receive the reference treatment (R) whereas the other N/2 subjects are allocated to the test treatment (T). Such a design is often chosen to assess the bioequivalence of drugs with long half-lives preventing the use of each patient as his own control within the time constraints of drug development. We simulated BSV random effects with $\omega_{Ka} = \omega_{CL/F} = 22\%$ and $\omega_{V/F} = 11\%$, i.e., rather low BSV. For parallel trials, the period effects β_l^P , the sequence effects β_l^S , and the WSV $\kappa_{i,k,l}$ in the expression of the log of individual parameters (2) are null.

We also simulated a two-periods, two-sequences cross-over design (Figure 2), which is the goldstandard in bioequivalence trials. In these trials, the N/2 subjects of the first sequence (S_1) ¹⁷⁹ receive the reference (R) treatment at period 1 (P_1) , and the test (T) treatment at period 2 ¹⁸⁰ (P_2) , whereas the N/2 subjects of the second sequence (S_2) receive treatments in the reverse ¹⁸¹ order. We simulated BSV and WSV random effects with $\omega_{Ka} = \omega_{CL/F} = \omega_{V/F} = 50\%$, and ¹⁸² $\gamma_{Ka} = \gamma_{CL/F} = \gamma_{V/F} = 15\%$, i.e., rather high BSV and rather low WSV. ¹⁸³

3.4 Implementation and evaluation

We evaluated the type I error and power of the MB-TOST on β_{AUC}^{Tr} and β_{Cmax}^{Tr} using the different approaches, at the nominal level $\alpha = 5\%$ on the different scenarios.

162

161

Five hundred data sets were simulated per scenario, using the R software.	188
The parameters of the NLMEM were estimated using the SAEM algorithm. For the parallel	189
design, we used the R package saemix version 1.2 [19], and for the crossover design, we used	190
the monolix software version 2018R2 [20].	191
We used the same parameterisation with both softwares; 10 Monte Carlo Markov chains, 300	192
iterations in the exploratory phase, and 100 iterations in the smoothing phase.	193
	194
For the Asympt approach, the FIM was obtained by linearisation.	195
For the Post approach, we used the Rstan package with 1000 iterations and 100 burn-in, so	196
that we obtained 900 samples.	197
For the Boot approach, we simulated $B=250$ data sets.	198
	199
All calculations were run on an i7-5600 U CPU computer, with frequency 2.60 GHz, 4 cores, 8	200
GB of RAM.	201

187

202

203

4 Results

4.1 Two-arms parallel

For both the sparse and rich designs, the Relative Biais (RBiais) and the Relative Root Mean Square Errors (RRMSE) were below 10% for the fixed effects and close to 0 for the treatment effect coefficients (Table I in supplementary material 1). For the BSV and residual error standard deviations, there was a upward trend in the RBiais, below 10% for the rich design and up to 30% for the sparse design. The RRMSE also increased for the sparse design, up to 121% for the additive residual error standard deviation. Yet, there was no major concern with the estimation of the NLMEM parameters. 204

On the rich design, MB-TOST conserved a nominal type I error with all different SE calculations (Figure 3). On the sparse design with N=40, MB-TOST for β_{AUC}^{Tr} using the asymptotic SE led to an inflated type I error (Figure 3). However, using the alternative calculations of the SE, the inflation was corrected.

In supplementary material 2, we evaluate the proposed approaches to compute the SE along ²¹⁵ with both MB-TOST and MB-BOT on a sparser design (with N=12 subjects). Then, we ²¹⁶ further explore the relationship between $SE(\beta_{SP}^{Tr})$ and the MB-TOST type I error and derive ²¹⁷ a critical threshold when MB-TOST no longer controls its nominal level and MB-BOT should ²¹⁸ be used instead. ²¹⁹

The simulated power of MB-TOST using the different SE calculations were of similar order and 220 of reasonable size > 70% (Table I). We observe higher power to conclude to bioequivalence on 221 C_{max} compared to AUC as we simulated $\omega_{Cmax} = 10\%$ and $\omega_{AUC} = 22\%$, respectively. 222 With regard to computational times, Asympt and Gallant approaches took a few seconds per 223 data set, whereas running Post took a few minutes, and Boot close to 1 hour. In fact, we did 224 not compute the bootstrap-based SE on the sparse design with N=20 (scenario simulated under 225 the null only), given its computational burden and the good performances of the Gallant and 226 Post alternatives. 227

4.2 Two-periods, two-sequences cross-over

The Rbias and RRMSE on all parameters for the scenario with a sparse design, which we ²²⁹ expected to be the most challenging under the null, are listed in Supplementary Material 1, ²³⁰ Table II. For the fixed effects and treatment effect coefficients, all Rbias were below 5% and ²³¹ the RRMSE were below 25%. For the BSV, WSV and residual error standard deviations, the ²³² Rbias showed a downward trend (but for γ_{Ka}), and the RRMSE were below 40%. Again, there ²³³ was no major concern with the estimation of the NLMEM parameters. ²³⁴

MB-TOST for β_{AUC}^{Tr} controlled its nominal level using all SE calculation whatever the design 235 (Figure 4). Whereas MB-TOST for β_{Cmax}^{Tr} using the asymptotic SE obtained an inflation of 236 the type I error at 7.6% on the rich design and 7.8% on the sparse design. This inflation was 237 corrected using all the alternative SE calculations. Given its computational burden and the 238 good performance of other alternative SE calculations, we only evaluated the bootstrap-based 239 SE on the most challenging design, i.e., the sparse design where it took about 5 hours per data 240 set. 241

MB-TOST for β_{AUC}^{Tr} and β_{Cmax}^{Tr} obtained extremely high power (>95%) using all SE calculations whatever the design (Table II).

5 Discussion

In this work we proposed, and evaluated by simulations, three alternative SE calculations to 246 correct for the type I error inflation of MB-TOST in PK bioequivalence studies with sparse 247 sampling. MB-TOST using the three alternative SE calculations provided both a controlled 248 nominal type I error and satisfactory power, on parallel and cross-over studies with rich and 249 sparse sampling. Here, we used B=250 iterations for bootstrap. This relative small number 250 nonetheless enabled the bootstrap approach to provide a controlled type I error. However, 251 its computational burden proved particularly limiting, especially given the good performances 252 of the SE calculations based on the work of Gallant [6] and the *a posteriori* distribution [9]. 253

245

244

Besides sparse sampling, products with high PK variability present another methodological 258 challenge in bioequivalence studies. Already, Haidar et al. proposed a scaling approach setting 259 a constraint on the geometric mean ratio [21] and the US Food and Drug Administration's 260 Office of Generic Drugs developed a reference-scaled average bioequivalence approach [22]. In 261 [12], Möllenhoff et al. proposed a new test, the MB-BOT, more appropriate for drugs with high 262 variability, when the sample size is not large enough. In Supplementary Material 2, we showed 263 that MB-BOT can also benefit from alternative SE calculations in PK BE studies with sparse 264 sampling. Further, we derived a threshold for the treatment effect SE above which MB-BOT 265 should be preferred to MB-TOST. 266

One limitation of the present work is the number of simulated datasets for each scenario un-267 der consideration. We choose to simulate 500 data sets because of the computational burden 268 and because we could effectively compare the approaches in term of type 1 error. Another 269 non-negligible limitation is the use of the simulated model to perform the MB-TOST. Indeed, 270 we did not investigate the robustness to model misspecification, or consider a model averaging 271 approach [23]. However we reckon that when bioequivalence studies are performed, there exists 272 some accumulated knowledge on the drug PK model (resulting from either a bottom-up or a 273 top-down approach), at least in the reference treatment group. 274

Finally, statistical methods have recently been proposed to control the nominal type I error in ²⁷⁶ bioequivalence studies using adaptive designs [24]. This methods rely on an adaptation of the ²⁷⁷ NCA-TOST and we believe there is a case for exploring these methods using MB-TOST, and ²⁷⁸ non-asymptotic SE for PK bioequivalence studies with sparse sampling. ²⁷⁹

281

280

275

6 Conclusion

We recommend to use non-asymptotic SE, based on the *a posteriori* distribution of the treatment effect coefficient, to test for bioequivalence on pharmacokinetic studies with sparse sampling with MB-TOST. 284

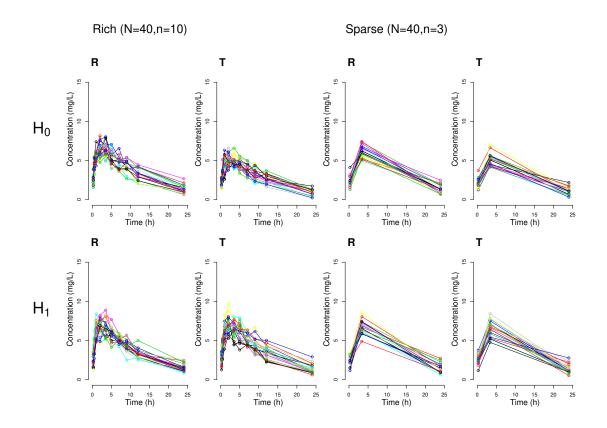

Figure 1: Spaghetti plots of simulated concentrations versus time for the two-arms parallel design under H_0 (top) and H_1 (bottom) for rich (columns 1 and 2) and sparse (columns 3 and 4) designs, in the reference (R, columns 1 and 3) and the test (T, columns 2 and 4) treatment groups.

Table I: Estimated power of MB-TOST on β_{AUC}^{Tr} and β_{Cmax}^{Tr} , using the different SE calculations, for the parallel rich and sparse designs on the 500 data sets.

	Rich (n=10)		Sparse (n=3)		
	β_{AUC}^{Tr}	β_{Cmax}^{Tr}	β_{AUC}^{Tr}	β_{Cmax}^{Tr}	
Asympt	0.830	1.000	0.804	1.000	
Gallant	0.782	1.000	0.762	0.998	
Post	0.772	0.966	0.712	0.990	
Boot	0.832	1.000	0.800	1.000	

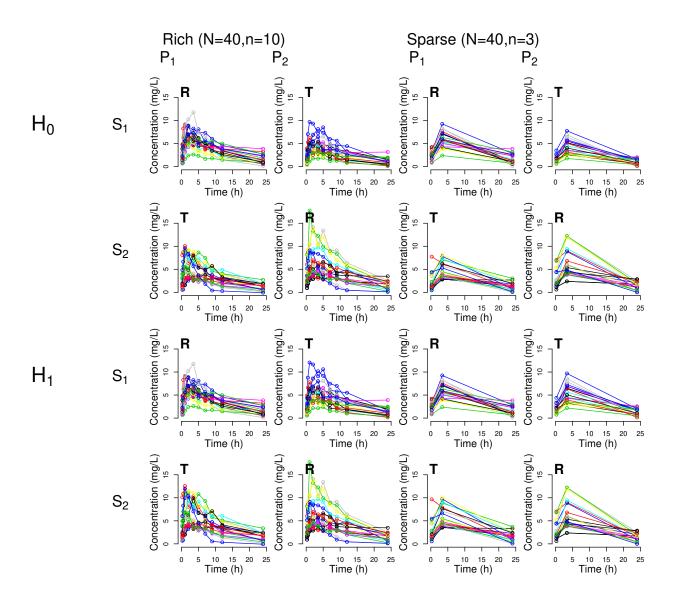

Figure 2: Spaghetti plots of simulated concentrations versus time for the 2-periods 2-sequences (S_1, S_2) cross-over design under H_0 (lines 1 and 2) and under H_1 (lines 3 and 4) for rich (columns 1 and 2) and sparse (columns 3 and 4) designs, in period 1 (P_1 , columns 1 and 3) and period 2 (P_2 , columns 2 and 4).

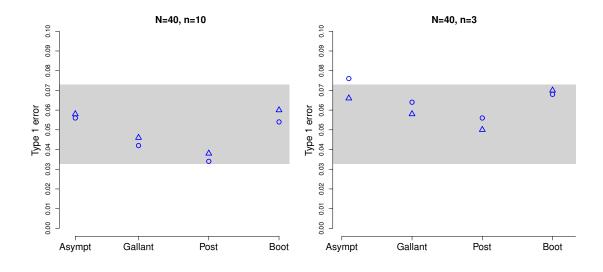

Figure 3: Type I errors of MB-TOST on β_{AUC}^{Tr} (o) and on β_{Cmax}^{Tr} (\triangle) using the different SE calculations on the parallel rich (left), and sparse (right) designs. The 95% prediction interval around 0.050 for 500 simulated data sets is indicated in grey ($PI_{95\%}(0.050) = [0.0326; 0.0729]$).

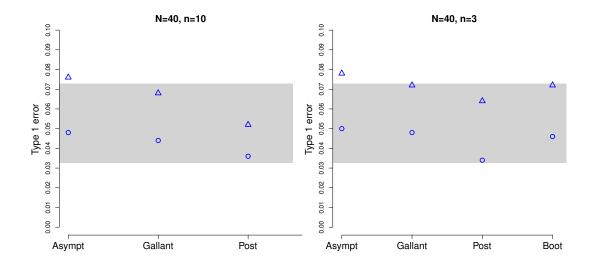

Figure 4: Type I errors of MB-TOST on β_{AUC}^{Tr} (o) and β_{Cmax}^{Tr} (Δ) using the different SE calculations on the cross-over rich (left) and sparse (right) designs. The 95% prediction interval around 0.050 for 500 simulated data sets is indicated in grey ($PI_{95\%}(0.050) = [0.0326; 0.0729]$).

Table II: Estimated power of MB-TOST on β_{AUC}^{Tr} and β_{Cmax}^{Tr} using the different SE calculation, for the cross-over rich and sparse designs.

	Rich (n=10)		Sparse (n=3)	
	β_{AUC}^{Tr}	β_{Cmax}^{Tr}	β_{AUC}^{Tr}	β_{Cmax}^{Tr}
