A Confidence Interval for Combined Univariate Economic Forecasts

Joachim Hartung and Doğan Argaç

Department of Statistics, University of Dortmund,
D–44221 Dortmund, Germany.

Abstract

Research in combining of economic forecasts made by several research institutes on the same economic variable has focused on estimation, hoping that the combined forecast will be improved by taking into account the expert opinions of the institutes. We provide a confidence interval on the combined forecast. A scoring of the individual institutes is proposed using their historical performance in forecasting.

Key words: Heterogeneous variances; Expert opinion; Confidence interval.

1 Introduction

Consider the situation where one has several forecasts on the same quantity, e. g. several economic research institutes forecast an important economic variable. Interest is in combining the individual forecasts to improve the accuracy of the forecast. Since by way of combining several forecasts one takes into account several expert opinions, one expects a better performance of the combined forecast. However, it is rarely observed that the simply average of the individual forecasts is beaten by more sophisticated methods. Klapper (1998, 1999, 2000) discusses rank–based techniques for combining forecasts. There is little known about confidence intervals on the combined forecast in this area.

In this paper, we give several confidence intervals on the combined forecast which are of approximate nature. The confidence intervals are derived using analysis of variance as a main tool. Some simulation results on the properties of the confidence intervals are provided. Finally, the confidence intervals are applied on German economic data.

2 A statistical model for combining forecasts

We consider the following model

$$y_i \sim N(\mu, \alpha_i), \tag{2.1}$$

where y_i denotes the forecast of the i–th institute, and μ represents the true unknown quantity, $i = 1, \ldots, K$, $K > 2$. Note that we assume that the variances α_i are heteroscedastic. Confidence intervals and tests are discussed in a related heteroscedastic ANOVA model by Hartung and Argaç (2002a, 2002b) and Hartung and Knapp (2000).

We estimate the mean μ by a weighted average of the individual forecasts y_i,

$$y = \sum_{i=1}^{K} b_i^2 \cdot y_i, \tag{2.2}$$

where b_i^2 denotes the weight which is given to the i–th institute by some scoring process. We assume that the weights are normed

$$\sum_{i=1}^{K} b_i^2 = 1, \tag{2.3}$$

and we also assume that $b_i^2 < 1/2$, that is we exclude the possibility that one particular institute dominates the rest. Consider now the following quadratic form, see also Hartung, Böckenhoff and Knapp (2002),

$$u_{ib}^2 = b_i^2 \cdot \left(y_i - \sum_{j=1}^{K} b_j^2 \cdot y_j \right)^2, \tag{2.4}$$

which can be interpreted as a weighted quadratic deviation of each individual forecast from the weighted average of the individual forecasts of each institute. Let $\beta_i = b_i^2 \cdot \alpha_i$, and one can derive explicitly the important moments of the quadratic form u_{ib}^2,

$$E(u_{ib}^2) = (1 - 2 \cdot b_i^2) \cdot \beta_i + b_i^2 \cdot \sum_{j=1}^{K} b_j^2 \cdot \beta_j =: e_i(b, \beta), \tag{2.5}$$

$$var(u_{ib}^2) = 2 \cdot e_i(b, \beta)^2, \tag{2.6}$$

$$Cov(u_{ib}^2, u_{jb}^2) = 2 \cdot b_i^2 \cdot b_j^2 \cdot \left(\sum_{k=1}^{K} b_k^2 \cdot \beta_k - \beta_i - \beta_j \right) =: 2 \cdot e_{ij}(b, \beta)^2. \tag{2.7}$$

We need to estimate the variance of the combined forecast and of each individual forecast, and for this purpose we use quadratic functions of the individual forecasts as estimators. The variance of the combined forecast is estimated with an unbiased positive (PSD–MINQUE) variance estimator which is given by, see also Hartung, Böckenhoff and Knapp (2002),

$$\widehat{var}(y)_{psd} = \frac{1}{1+\sum_{k=1}^{K}\frac{b_k^4}{1-2b_k^2}} \cdot \sum_{i=1}^{K}\frac{b_i^2}{1-2b_i^2}\cdot u_{ib}^2 \tag{2.8}$$

$$= \sum_{i=1}^{K} d_i \cdot u_{ib}^2. \tag{2.9}$$

The estimator of the variance of each forecast is given by a positive minimum biased variance estimator (PSD–MINQMBE) given by

$$\widehat{\alpha}_i = \frac{\sum_{j=1}^{K} u_{jb}^2 + \sum_{j=1}^{K} d_j \cdot u_{jb}^2}{\sum_{j=1}^{K} b_j^2 \cdot \widetilde{\alpha}_j} \cdot \widetilde{\alpha}_i, \tag{2.10}$$

where

$$\widetilde{\alpha}_i = \frac{1}{b_i^2} \cdot \frac{(1-b_i^2)^2}{(1-b_i^2)^4 + b_i^4 \sum_{j\neq i} b_j^4} \cdot u_{ib}^2. \tag{2.11}$$

Note here also that both estimators are given explicitly, see also Hartung, Böckenhoff and Knapp (2002) for a detailed derivation. Under suitable conditions these estimators are consistent, exist always and are unique. Surprisingly, the variance of the combined forecast can be unbiasedly estimated without any information about the variance of the individual forecasts.

We will construct the confidence interval using a pivotal quantity, and for this purpose we have to determine the distribution of the variance estimators. We

will approximate the distribution of the variance estimators by a suitable χ^2–distributions using moment matching, see Satterthwaite (1946) and Patnaik (1949). This leads to

$$\nu \cdot \sum_{i=1}^{K} d_i \cdot u_{ib}^2 / E(\sum_{i=1}^{K} d_i \cdot u_{ib}^2) \sim \chi_\nu^2, \tag{2.12}$$

where

$$\nu = 2 \, \frac{[E(\sum_{i=1}^{K} d_i \cdot u_{ib}^2)]^2}{var(\sum_{i=1}^{K} d_i \cdot u_{ib}^2)}. \tag{2.13}$$

Now, this gives us the following pivot (nominator and denominator are independent)

$$\frac{y - \mu}{\sqrt{\sum_{i=1}^{K} d_i \cdot u_{ib}^2}} \sim t_\nu, \tag{2.14}$$

where

$$\nu = \frac{\left\{\sum_{i=1}^{K} d_i \cdot e_i(b, \beta)\right\}^2}{\sum_{i=1}^{K} d_i^2 \cdot e_i(b, \beta)^2 + \sum_{i=1}^{K} \sum_{\substack{j=1 \\ i \neq j}}^{K} d_i \cdot d_j \cdot e_{ij}(b, \beta)^2}. \tag{2.15}$$

In practice, the unknown quantities have to be replaced by estimators, and here we use $\widehat{\beta}_i = b_i^2 \cdot \widehat{\alpha}_i$.

Now, we are in the position to derive the confidence intervals which are of course of approximate nature only.

$$K_1 : \quad y \mp t_{\nu;1-\alpha/2} \cdot \sqrt{\sum_{i=1}^{K} d_i \cdot u_{ib}^2} \tag{2.16}$$

$$K_2 : \quad y \mp u_{1-\alpha/2} \cdot \sqrt{\sum_{i=1}^{K} d_i \cdot u_{ib}^2} \tag{2.17}$$

$$K_3: \quad y \mp t_{K-1;1-\alpha/2} \cdot \sqrt{\sum_{i=1}^{K} d_i \cdot u_{ib}^2} \tag{2.18}$$

The first interval is the approximate interval derived using the t–distributed pivot, the second version is obtained if one replaces the quantile of the t–distribution with the quantile of the standard normal distribution for large degrees of freedom. The last version is obtained if one ignores the heteroscedastic variances. Now, we have to specify the weights b_i^2. We suggest the following choice of the weights:

$$b_i^2 = \frac{\sum_{j=1}^{L} \left(y_{ij} - y_j^w\right)^{-2}}{\sum_{i=1}^{K} \sum_{j=1}^{L} \left(y_{ij} - y_j^w\right)^{-2}}, \tag{2.19}$$

where y_{ij} denotes the forecast of the i–th institute for some economic variable in the j–th time period or year and y_j^w denotes the true realized value in the j–th time period or year. Hence, each institute is scored taking into account its historical performance in forecasting in the last L time periods or years. We consider quadratic deviations of each forecast from the true value.

3 Monte Carlo results

Since the intervals we constructed are of approximate nature, we conducted a simulation experiment to check their validity with respect to the actual confidence coefficients and lengths of the proposed confidence intervals. We considered $K = 7$ and $K = 14$ institutes. The weights b_i^2 are chosen to be equal, in a second scenario the weight of one institute is large compared to the other weights which are chosen to be equal, and finally, the weights are chosen to be almost equal. The variances of the individual forecasts are homoscedastic and heteroscedastic. We paired small variances with small weights and small variances with large weights. We draw samples from the normal and from a centered χ^2–distribution with a few degrees of freedom to cover also the case of non–normal observations. The number of repetitions in the simulations is 1000. In the simulations, we give summary statistics on the degrees of freedom of the approximate t–distribution. We report the bias, the standard deviation and the root mean square error (RMSE) of the variance estimators given in (2.10). We provide the empirical confidence level of the intervals at the nominal level of 90% and 95%, the lower and the upper confidence limits and the corresponding widths of the confidence intervals.

The main result is that, in general, the intervals K_1 and K_3 are conservative, the confidence interval K_2 also attains acceptable levels, but might become liberal under certain circumstances.

4 Data analysis

We applied the confidence intervals to German economic data. We used the data on GDP from seven major economic research institutes from 1984–1996. The data are described in Klapper (1998). For the first forecast, that is for 1987, we used the data from 1984–1986. The true values are given in the next table:

Table 1: True values of GDP.

Year	Value
1987	1.9
1988	3.7
1989	3.3
1990	4.7
1991	3.7
1992	1.6
1993	-1.7
1994	2.4
1995	1.9
1996	1.4

We give the weights b_i^2, the variance estimators given in (2.10) and (2.11), the variance of the combined forecast given in (2.8), the degrees of freedom of the approximate t–distribution, the combined forecast given in (2.2), and finally, the confidence intervals at nominal level of 90% and 95%.
