Chapter 1

Introduction

A fundamental property of nucleons (protons or neutrons) is that they carry spin $\frac{1}{2}$ and obey the appropriate Fermi-Dirac statistics, i.e., they are spin-$\frac{1}{2}$ fermions. As is indicated by their name, nucleons are the building blocks of atomic nuclei, and their spin plays a crucial role in determining the properties of these nuclei. For example, we can compare $^3$H made up of one proton and two neutrons with $^3$He made up of two protons and one neutron. In the dominant state of zero orbital angular momentum (S-wave) of the nucleons, the Pauli exclusion principle requires the two neutrons and the two protons, respectively, to be anti-aligned in spin. Thus we can expect that the nuclear spin effects mirror those of the unpaired nucleon. This can be seen in spin dependent quantities, like the magnetic moments: $\mu_H = 2.9790 \simeq 2.7928 = \mu_p$ and $\mu_{^3\text{He}} = -2.1276 \simeq -1.9130 = \mu_n$ [1, 2]. An even closer agreement is obtained when we compare

$$\frac{1}{2} (\mu_H + \mu_{^3\text{He}}) = 0.4257 \simeq 0.4399 = \frac{1}{2} (\mu_p + \mu_n),$$

since then the difference in the interactions of protons and neutrons averages out. The remaining deviation can be attributed to higher orbital angular momentum states. Though spin certainly is an important property of the nucleon, as our little example has shown, the explanation of its origin is still fraught with uncertainties.

Since the advent of the QCD improved parton model, we know that the nucleon is not an elementary particle itself, but rather a bound state of more elementary particles (quarks, antiquarks and gluons) possessing rich internal structure. Hence high energy studies of the nucleon spin have always been challenging experimentally and theoretically. Determining the polarized gluon density $\Delta g(x, \mu^2)$ is currently a hot topic in this field. In order to better understand how the gluon polarization became a major issue, we will briefly sketch the historical development, starting with quark models which do not contain gluons at all. Several reviews of spin physics have been written, which offer a very complete account of the past and present status, see for example [3, 4]. In these references one can find the details we are omitting here. Take a simple valence quark model in which the entire nucleon spin is generated by two $u_v$-quarks plus one $d_v$-quark for the proton and by two $d_v'$-quarks plus one $u_v'$-quark for the neutron. We assume that there is no orbital
angular momentum of the quarks and that the sea quarks carry no net spin. Since the quarks are spin-$\frac{1}{2}$ particles, the Pauli exclusion principle would require again that the spins of the two quarks with same flavor have to be anti-aligned, so that the nucleon spin would mirror the spin of the unpaired quark, in complete analogy to the $^3\text{H}$ and $^3\text{He}$ case. However, this simple picture cannot be true: the $\Omega^-$ baryon has spin $\frac{3}{2}$ and consists of three strange quarks in an $S$-wave. Thus it has three spin aligned quarks of the same flavor in spite of the Pauli exclusion principle! The solution is of course the new quantum number “color” of $SU(3)_{\text{color}}$. If the three $s$-quarks of the $\Omega^-$ all carry different color, then they can occupy the same spin state. But the direct relation of the nucleon spin to the spin of the unpaired quark is now lost, since there is no reason why color should not play a similar role in this case as well.

So let us just generally assume that color guarantees the absence of completely identical fermions in the wave function. Then we have to consider contributions of both valence quark flavors to the nucleon spin. The total polarization of quarks with flavor $q$ will be denoted by $\Delta q$ and similarly for the antiquarks. The total valence quark polarizations are then given by $\Delta u_v = \Delta u - \Delta \bar{u}$ and $\Delta d_v = \Delta d - \Delta \bar{d}$. Hence we expect\footnote{The model is flawed, since it makes no distinction between constituent and current quarks.}

\[
\frac{1}{2} |_{\text{proton}} = \frac{1}{2} \sum_q (\Delta q + \Delta \bar{q}) \equiv \frac{1}{2} \Delta \Sigma \tag{1.2}
\]

\[
= \frac{1}{2} (\Delta u_v + \Delta d_v) \tag{1.3}
\]

In (1.2) we have assumed that the quarks carry the spin and in (1.3) that the sea quarks have no net polarization. The same relation holds also for the neutron, but we have to exchange $u$- and $d$-quarks due to isospin symmetry. So we can write for the magnetic moments

\[
\mu_p = \mu_u \Delta u_v + \mu_d \Delta d_v \; , \quad \mu_n = \mu_d \Delta u_v + \mu_u \Delta d_v \; , \tag{1.4}
\]

where we always use the polarizations for a proton. In a $SU(6)$ model compatible\footnote{One obtains $\Delta \bar{u} = \Delta \bar{d} = \Delta s = \Delta \bar{s} = 0$ for $SU(6)$ symmetry.} with (1.3), which is constructed from $SU(3)_{\text{flavor}} \otimes SU(2)_{\text{spin}}$, we find for the $SU(6)$-symmetric wave function $\Delta u_v = \frac{4}{3}$ and $\Delta d_v = -\frac{1}{3}$, see for example [5]. Using the simple assumption $\mu_u = -2\mu_d$, because of the difference in charge $e_u = -2e_d$, one finally predicts with (1.4)

\[
\frac{\mu_n}{\mu_p} = \frac{2}{3} \exp \simeq -0.685 \; , \tag{1.5}
\]

in fairly good agreement with experiment.

But this naïve model soon runs into difficulties when being compared to other experimental results. For example it predicts for the $\beta$-decay constants $F = \frac{2}{3}$ and $D = 1$, in
conflict with the experimental\textsuperscript{3} measurements [1, 6]
\[
\begin{align*}
\text{neutron } \beta \text{- decay: } & \quad F + D = 1.2670 \pm 0.0035 , \\
\text{hyperon } \beta \text{- decay: } & \quad 3F - D = 0.579 \pm 0.025 .
\end{align*}
\]
(1.6)

One can try to fix the problem by rewriting (1.2) as
\[
\frac{1}{2} \rho_{\text{proton}} = \frac{1}{2} \Delta \Sigma + L_z^q ,
\]
(1.7)

where we now introduce the orbital angular momentum of the quarks $L_z^q$ as a relativistic effect [7, 8]. For vanishing strange sea polarization $\Delta s = \Delta \bar{s} = 0$, we have $\Delta \Sigma = 3F - D$ and hence we can accommodate the experimental result by assigning $L_z^q = 0.2105$, which indicates a sizeable contribution of quark orbital angular momentum to the proton spin!

In order to understand the impact of the next experimental result, we need to take strange quarks into account explicitly
\[
\begin{align*}
F + D \underset{\text{iso}}{\sim} A_3 &= \Delta u + \Delta \bar{u} - \Delta d - \Delta \bar{d} , \\
3F - D \underset{\text{flavor}}{\sim} A_8 &= \Delta u + \Delta \bar{u} + \Delta d + \Delta \bar{d} - 2(\Delta s + \Delta \bar{s}) , \\
A_0 &= \Delta \Sigma = \sum_q (\Delta q + \Delta \bar{q}) = A_8 + 3(\Delta s + \Delta \bar{s}) .
\end{align*}
\]
(1.8)

The first moment of the structure function $g_1$ measured in lepton-nucleon scattering, for details see for example [4], can be written in this form
\[
\Gamma_{1}^{p,n} = \frac{1}{2} \left( \pm \frac{1}{6} A_3 + \frac{1}{18} A_8 + \frac{2}{9} A_0 \right) = \begin{cases} 0.186 \pm 0.004 \\ -0.025 \pm 0.004 \end{cases} + \frac{1}{3} (\Delta s + \Delta \bar{s}) ,
\]
(1.9)

by simply inserting the values of (1.6). In the QCD improved parton model discussed below, (1.8) and (1.9) remain valid in LO for the first moments of the parton densities. We can now derive the (Gordan-)Ellis-Jaffe sum rule [9] $\Gamma_{1,\text{EJ}} \simeq 0.186$ by assuming $\Delta s = \Delta \bar{s} = 0$ in (1.9). However, in the Bjorken sum rule [10] for the difference $\Gamma_{1}^{p} - \Gamma_{1}^{n} = \frac{1}{6}(F + D) \simeq 0.2112$, the dependence on the strange quarks and on $A_8$ cancels, so that this result relies only on isospin symmetry. The combined experimental result of the EMC and SLAC collaborations\textsuperscript{4}, see [11] and references therein, disagrees with the Ellis-Jaffe prediction
\[
\Gamma_{1}^{p} = 0.126 \pm 0.018 \quad \sim \quad \Delta s + \Delta \bar{s} \simeq -0.18 \quad \sim \quad \Delta \Sigma = 0.04 .
\]
(1.10)

\textsuperscript{3}The hyperon $\beta$-decay fit of [6] was performed using $F + D \overset{\text{old}}{=} 1.257$ and fitting $F/D$. With the new experimental value $F + D = 1.2670$ and their old value $3F - D = 0.579$, we obtain $F/D = 0.573$ instead of their old fitted $F/D = 0.575 \pm 0.016$. Thus a re-fit is not needed for our purposes here.

\textsuperscript{4}We ignore the $\langle Q^2 \rangle = 10.7 \text{ GeV}^2$ (EMC), $4 \text{ GeV}^2$ (SLAC) dependence for the moment and add statistical and systematic errors in quadrature.
So experiment suggests that a large negative strange sea polarization drives the contribution of the quarks to the proton spin to basically zero: $\Delta \Sigma \simeq 0$. Later experiments agree within errors with this result, see for example [4].

This counter-intuitive result triggered the famous “spin crisis”, though it should have been more appropriately named “spin surprise” and “intuition crisis”, because there is a priori nothing wrong with the solution we have obtained in (1.10). But we certainly have come a long way from the naïve assumption $\Delta \Sigma = 1$ we started with in (1.2). By inspecting the equations (1.8) and (1.9), we find that one still can achieve a $\Delta s = \Delta \bar{s} = 0$ solution, if the $SU(3)_{flavor}$ symmetry assumption $A_0 = 3F - D$ is discarded. But we must leave the quark model level of studies anyway, since we note that the Bjorken sum rule also seems to be in trouble. The SLAC E143 experiment [12] finds $\Gamma_1^p - \Gamma_1^n = 0.163 \pm 0.017$ at $Q^2 = 3$ GeV$^2$, to be compared with the value $\Gamma_1^p - \Gamma_1^n \simeq 0.2112$ obtained above. However, the CERN SMC measurement at $Q^2 = 10$ GeV$^2$ [13] gives $\Gamma_1^p - \Gamma_1^n = 0.195 \pm 0.029$ and thus agrees much better with our quark model prediction. Since the Bjorken sum rule is based only on isospin invariance, it is not as easily cast aside as the Ellis-Jaffe sum rule. A better agreement with growing $Q^2$ immediately suggests that perturbative QCD corrections may help. Indeed one finds that the perturbative QCD corrections up to $O(\alpha_s^3)$ [14] are all negative

$$\Gamma_1^p - \Gamma_1^n = \frac{1}{6}(F + D) \left[ 1 - \frac{\alpha_s(Q^2)}{\pi} - 3.5833 \left( \frac{\alpha_s(Q^2)}{\pi} \right)^2 - 20.2153 \left( \frac{\alpha_s(Q^2)}{\pi} \right)^3 \right],$$

(1.11)

and reasonable agreement with the experiments can be achieved when a running coupling $\alpha_s(Q^2)$ is used, see [4] and references therein. But it should be clear that perturbative QCD corrections come with a price, namely scale dependence of the partons and the introduction of gluons. Also the situation with respect to the Ellis-Jaffe sum rule does not significantly change due to the introduction of QCD corrections, see our discussion of a QCD fit below.

In conclusion, we see that additional experimental results forced us to adopt more sophisticated theoretical approaches, until we finally made use of perturbative QCD corrections to the Bjorken sum rule. So we should now consider the complete QCD improved parton model for consistency, which in hindsight would have been a good starting point anyway. For the spin of the proton one must then write instead of (1.7)

$$\frac{1}{2} l_{\text{proton}} = \frac{1}{2} \Delta \Sigma_{n-1}(\mu_f^2) + \Delta g_{n-1}(\mu_f^2) + \tilde{L}_q(\mu_f^2) + \tilde{L}_g(\mu_f^2) ,$$

(1.12)

$$\Delta \Sigma(x, \mu_f^2) \equiv \sum_q [\Delta q(x, \mu_f^2) + \Delta \bar{q}(x, \mu_f^2)] ,$$

(1.13)

$$a_n \equiv \int_0^1 dx \ x^{n-1} a(x) ,$$

(1.14)

which introduces polarized parton densities, $\Delta q(x, \mu_f^2)$, $\Delta \bar{q}(x, \mu_f^2)$ and $\Delta g(x, \mu_f^2)$, depending on Bjorken $x$ and the factorization scale $\mu_f^2$. Their definition will be examined more
Table 1.1: First moments of GRSV standard densities taken from Tab. 1 in [15]. For these densities $\Delta s_{n=1} + \Delta s_{n=1} = 2\Delta s_{n=1}$. The total partonic angular momentum $L_z \equiv L_z^q + L_z^g$ is calculated using (1.12).

closely in the next chapter. The first moment, $n = 1$ in (1.14), of these densities has the interpretation we have been using in our quark models, i.e., corresponds to the total polarization carried by the partons of this type. Note that the first moment of the polarized gluon density $\Delta g(x, \mu_f^2)$ was introduced explicitly in the spin sum rule, as was a possible angular momentum contribution of the gluons $L_z^g$. Extracting the values to be inserted in (1.12) from experiment is a challenging task. Currently no direct experimental information on the total partonic angular momentum $L_z \equiv L_z^q + L_z^g$ is available, it can only be derived indirectly from the fitted values for $\Delta \Sigma_{n=1}$ and $\Delta g_{n=1}$ via (1.12).

For illustration we show in Tab. 1.1 for a particular next-to-leading order (NLO) $\overline{\text{MS}}$ set of parton distributions, the GRSV standard$^5$ densities [15], the scale dependence of the first moments of the parton distributions and of the inferred parton angular momentum. The polarization of the strange sea $\Delta s_{n=1} + \Delta s_{n=1}$, which here is equal to $2\Delta s_{n=1}$, is shown separately. Since this particular fit assumes $SU(3)_{\text{flavor}}$ symmetry, as expected a large negative strange sea polarization is needed to keep $\Delta \Sigma_{n=1}$ fairly small. We see that the quark sector has only a weak scale dependence. In contrast, the gluon polarization evolves rapidly and in response the angular momentum changes quickly as well. We would like to point out a particularly satisfying feature of this fit: at the low starting scale 0.34 GeV$^2$ one finds almost zero angular momentum. This suggests an intuitive picture, in which the gluon polarization and partonic angular momentum are built up at the same time by increasing gluon radiation for rising $\mu_f^2$. Note however that the results are scheme dependent, i.e., are only directly valid for NLO $\overline{\text{MS}}$.

The good news is that the QCD improved parton model describes the data well, see for example [15]. The bad news are hidden in the uncertainties of the fit. Though the quark sector is fairly well determined, the gluon density can be varied freely without influencing the quality of the fit significantly. We will not try to describe the plethora of NLO QCD fits that have been published recently. There are several fits which are a bit more up-to-

$^5$This fit uses the old value $F + D = 1.2573$. The authors also present a “valence” fit which does not assume $SU(3)_{\text{flavor}}$ symmetry and starts with zero strange sea polarization, see [15] for details.
date concerning the used data than the densities we will employ, see for example [16] for two recent ones. From a practical point of view, we note that only the older fits [15, 17, 18] used by us provide \((x, \mu_f^2)\)-grids of their evolved parton distributions. The interpolation routine that constructs the parton distributions at arbitrary \((x, \mu_f^2)\)-points from the grids is very fast. The newer fits by other groups just state the \(x\)-shape of the parton densities at a starting scale \(\mu_{f0}^2\), i.e., one has to evolve them to other \(\mu_f^2\) values. Since the Monte Carlo integrations for the hadronic cross sections require million-fold access to the parton distributions at varying \(x\) and \(\mu_f^2\), employing parton evolution every time would be far too time-consuming. Furthermore, the crucial problem of the basically undetermined gluon density is not resolved in the newer fits and so the uncertainties would remain basically unchanged if we used the newer densities.

![Figure 1.1: \(\Delta \Sigma\) and \(\Delta g\) uncertainties as obtained in the SMC fit [19]. Shown are the best fits (solid line) and the statistical (crossed hatch band), experimental systematic (vertically hatched), and theoretical (horizontally hatched) uncertainties as a function of \(x\) at the evolution starting scale \(\mu_{f0}^2 = 1\text{GeV}^2\). Note that the densities are obtained in the AB scheme [20], but \(\Delta g(x, \mu_f^2)\) remains unchanged by a scheme transformation to \(\overline{\text{MS}}\). The figure shown here is part of Fig. 5 in [19].](image)

The extensive experimental and theoretical error analysis of the SMC fit [19] of polarized parton densities allows a particularly good estimate of these uncertainties. Part of the results are shown in Fig. 1.1, which has been extracted from their paper. Note that the densities shown there are in the AB scheme [20], not in \(\overline{\text{MS}}\). But the situation is basically the same for \(\overline{\text{MS}}\) and actually a scheme transformation from AB to \(\overline{\text{MS}}\) will
leave the gluon untouched\textsuperscript{6}. We see that the polarized quark singlet distribution \(\Delta \Sigma\) is already constrained appreciably by the data. However, the gluon distribution is only very badly constrained, in particular if we take the systematic and theoretical uncertainties into account. We can compare this to the unpolarized gluon density in the left part of Fig. 1.2. This figure has been extracted from \cite{21} and shows a not yet published fit to \(F_2\) scaling violations of the H1 Collaboration, for details see \cite{21}. Note that the uncertainties shown are probably an overestimate, since only a subset of the available unpolarized data has been used. Even taking into account that the uncertainties would be somewhat larger if the unpolarized gluon density was shown at the same low scale used in Fig. 1.1, in particular at small \(x\), we can clearly see the big lead in precision of the unpolarized fit.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{unpolarized_gluon_density.png}
\caption{Uncertainty of the unpolarized gluon density \(g(x, \mu^2) = Q^2\) from the H1 fit to scaling violations \cite{21} (left) and comparison of this fit to the gluon unfolded from charm structure function DIS and photoproduction data for \(D^+\) \cite{22} (right). The inner dark band of the gluon density shows experimental, the outer light band theoretical uncertainties. The figure shown here is Fig. 14 of \cite{21}.}
\end{figure}

The quality of the determination of \(g(x, \mu^2)\) from measurements of the structure function \(F_2\) in deep inelastic scattering (DIS) may be surprising, since it is hampered by the absence of direct couplings of the gluons to the electroweak probes (\(\gamma^*, Z, W^\pm\)). However, Fig. 1.2 demonstrates, that the increasingly precise \(F_2\) data from HERA still serve

\textsuperscript{6}However, their separately fitted \(\overline{\text{MS}}\) gluon density does not exactly match their A6 gluon density transformed to \(\overline{\text{MS}}\). No picture of the \(\overline{\text{MS}}\) uncertainties is presented in \cite{19}.
to constrain the small-\(x\) behavior of \(g(x, \mu^2)\) indirectly in the region \(10^{-1} \lesssim x \lesssim 10^{-2}\) with satisfying accuracy from the observed scaling violations \(\partial F_2(x, \mu^2) / \partial \mu^2\). To determine \(g(x, \mu^2)\) over the entire \(x\) region, i.e., also at larger values of \(x\), studies of exclusive reactions like direct photon or di-jet production, where the gluon already enters in leading order (LO), are often used in global fits. Such measurements are often experimentally much more involved and less precise than inclusive DIS. Nevertheless, our knowledge of the unpolarized gluon density has greatly improved in the past few years, except in the region \(x \gtrsim 0.1\), where the situation is still far from being satisfactory. Here the relative uncertainty in \(g(x, \mu^2)\) grows to about 100\% [23, 24], which is not easily seen in Fig. 1.2, due to the small size of the gluon density.

The long list of spin-dependent DIS experiments [25] and the recently completed NLO framework for the evolution of the polarized parton densities [26, 27] may lead to the expectation that the polarized gluon distribution \(\Delta g(x, \mu^2)\) should be known with almost similar accuracy as \(g(x, \mu^2)\) by now. This is not the case, as we see clearly comparing Fig. 1.1 and Fig. 1.2. Consequently \(\Delta g_{n=1}(\mu^2)\) can be estimated at best with an error of 100\% for the time being. There are three main reasons why at present it is difficult to pin down \(\Delta g(x, \mu^2)\):

- The measurements of the nucleon spin structure function \(g_1\), the polarized observable analogous to the unpolarized structure function \(F_1\), are still in a “pre-HERA” phase. The lever arm in \(\mu^2 = Q^2\) of the fixed target experiments [25] is by far not sufficient to constrain \(\Delta g(x, \mu^2)\) from scaling violations \(\partial g_1(x, \mu^2) / \partial \mu^2\).

- As already mentioned, the unpolarized gluon density is also constrained by several exclusive reactions, but corresponding measurements in the polarized case are still missing.

- There is no energy-momentum sum rule for spin-dependent parton densities! In the unpolarized case this constraint on the second moments \(\Sigma_{n=2}(\mu^2) + g_{n=2}(\mu^2) = 1\) is very important for the determination of the gluon density, since it relates the gluon densities to the directly probed, and hence more precisely known, quark densities. In addition, the spin-dependent parton densities are not required to be positive definite.

We cannot hope to use (1.12) similarly to the energy-momentum sum rule in the unpolarized case, until independent experimental information on the parton angular momentum is available. The small-\(x\) region of \(g_1\) could be explored at HERA, if the option to longitudinally polarize also the proton beam [28] will be realized in the future. However, first measurements of \(\Delta g\) in exclusive reactions\(^7\) will be provided by the COMPASS fixed target experiment at CERN [31] and the BNL RHIC polarized \(pp\)-collider [32], which both soon will start taking data. Thus corresponding theoretical calculations are urgently needed.

\(^7\)The HERMES experiment has published such a measurement already [29]. But there are strong doubts concerning the applicability of perturbative QCD in this case [30].
Chapter 1. Introduction

We will now briefly describe the reactions investigated in our work, which are relevant for these experiments. For the determination of the gluon distribution, heavy quark \((Q = c, b)\) photoproduction

\[
\gamma g \rightarrow Q\bar{Q}
\]

is an obvious choice (an arrow denotes a longitudinally polarized particle from now on). The reconstruction of an open heavy quark state is experimentally feasible, and in LO only the photon-gluon fusion (PGF) process contributes\(^8\), as will be shown in the next chapter. This leads to the hope that an unambiguous determination of \(\Delta g\) can be performed. Thus polarized open charm photoproduction will be used by the upcoming COMPASS experiment [31] to measure \(\Delta g\). In the publications [34, 35], we have provided the first NLO QCD predictions for this process. The partonic results and phenomenological predictions of [34] and the presentation of the calculational methods and the stability investigations of [35] already provide the information needed for the experiments in a compact form. In this thesis we will provide much more technical detail and also extend all the phenomenological investigations. We hope that the methods collected here will provide a convenient reference for future NLO calculations. Also the problems related to choosing inconsistent schemes in [34, 35] for the phenomenological predictions have been corrected here\(^9\) according to [37]. Note that the right part of Fig. 1.2 suggests that photoproduction of charm is indeed a good process for determining the gluon distribution (here the unpolarized one). The agreement of the gluon density unfolded from the photoproduction measurement with the one obtained from the scaling violations is, within errors, perfect!

Similarly, gluon-gluon fusion producing heavy (anti)quarks

\[
\bar{q}q \rightarrow Q\bar{Q}
\]

is a promising candidate for extracting the gluon density in \(p\bar{p}\)-collisions. Of course here we also have the competing process of quark-antiquark annihilation \(q\bar{q} \rightarrow Q\bar{Q}\) already at LO, which plays a role at high \(p_T\). But the gluon induced reaction will dominate at small to medium \(p_T\), except if \(\Delta g\) is very small, and the high statistics and smaller \(x\) that can be reached due to the higher center of mass energy of a \(p\bar{p}\)-collider make this reaction a promising candidate for the extraction of \(\Delta g\). A progress report on the corresponding NLO calculation has been given in [38] and we extend our discussion of it considerably here. Note that all theoretical studies of the polarized reactions (1.15) and (1.16) have been performed in LO only so far [39, 40, 41, 33, 31]. However, LO estimates usually suffer from a strong dependence on the a priori unknown factorization and renormalization scales. Also there are new NLO subprocesses induced by a light quark replacing a gluon.

---

\(^8\)The on-shell photons in (1.15) cannot only interact directly, but also via their partonic structure. However, LO estimates of this unknown “resolved” contribution are small for COMPASS energies [33].

\(^9\)The partonic cross sections of [34, 35] were not calculated in the \(\overline{\text{MS}}\) scheme, as it was wrongly assumed there, but rather in the \(\overline{\text{MS}}\) scheme, see for example [36], and then convoluted with \(\overline{\text{MS}}\) parton densities. The numerical consequences of this inconsistency are small. The partonic results shown and used here are in the \(\overline{\text{MS}}\) scheme.
in the initial state. Here the question arises if there are kinematical regions in which this new subprocess can yield significant contributions and thus complicate a precise determination of $\Delta g$. NLO corrections are often more important for polarized differential cross sections, since they can oscillate. Small changes to the position of a zero crossing may then have large effects. Finally, the NLO corrections have been shown to be sizable near threshold and for high energies in the unpolarized case [42, 43, 44, 45, 46]. Clearly, a NLO calculation also for the spin-dependent case is warranted in order to provide a meaningful interpretation of the forthcoming experimental results.

In the next chapter we will introduce the notation and some basic methods used in our calculation of polarized processes. We will also derive the LO cross sections and the $2 \to 2$ phase space in $n = 4 + \varepsilon$ dimensions, which is needed for treating the spurious singularities in the NLO corrections by dimensional regularization. In Chap. 3 the methods used for the calculation of virtual loops are explained. Formulae for the integration of basic scalar loop integrals are provided and for demonstration we show the calculation of a box graph step by step. Next we explain how tensor loop integrals can be reduced to a small set of these basic scalar loop integrals by using the Passarino-Veltman decomposition technique [47]. The ultraviolet divergencies that occur in these loop integrals are cured by renormalization, so this is the topic of Chap. 4. We show how to derive renormalization counterterms from the QCD Lagrangian, calculate them explicitly, and finally discuss their application. In doing so we explain our scheme choice, a somewhat modified $\overline{\text{MS}}$ scheme, and briefly touch the subject of the running strong coupling $\alpha_s$.

The following chapter is concerned with the methods used for calculating the other type of NLO corrections, the real $2 \to 3$ contributions. We show how collinear and soft singularities arise in these contributions. Partial fractioning of angular phase space integrations is a major technical issue here, which we consider in detail. Finally we calculate the minimal number of basic angular integrals needed and introduce the method of phase space slicing to analytically cancel the infrared virtual against the soft real singularities. The only divergencies left after the cancellation are collinear ones and in Chap. 6 their removal by mass factorization is discussed. To this end we analyze the process $\bar{q} q \to Q\bar{q}$, in which the only occurring singularities are collinear. It is shown how one can absorb these divergencies in a re-definition of the parton densities and the subtraction terms for all relevant subprocesses are derived. The “evolution” of parton densities also emerges naturally from our discussion. In Chap. 7 we present our partonic results for photoproduction and hadroproduction in full detail. Formulae for the soft real, for the pole part of the hard real, and for the virtual plus soft contributions are provided. So-called “scaling functions” related to the total partonic cross section are used to present the results graphically\textsuperscript{10}. All the NLO results for photoproduction are presented. The same is true for hadroproduction, except for the virtual gluon contribution, which is almost finished and will be presented in a later publication. For the missing piece all necessary ingredients have been obtained already by the methods described in this thesis.

\textsuperscript{10} Due to the scheme problems of [34, 35], which are discussed in [37], these curves show the correct $\overline{\text{MS}}_m$ scheme results for the first time.
i.e., the matrix elements and tensor loop integrals have been calculated. Obtaining the final result is just a matter of putting all the parts together, but this is in practice a very time consuming job.

Thus in Chap. 8 we can present phenomenological studies only for NLO photoproduction. The dependence on the factorization and renormalization scales and on the heavy quark mass is investigated and the improved stability of the NLO calculation against variations of these scales becomes obvious. Next the possibility to enhance measured asymmetries by applying $p_T$-cuts is demonstrated, and this is used to provide improved predictions for the charm asymmetry at COMPASS [31] and for the bottom asymmetry at a possible future polarized HERA [28]. $y$- and $x_F$-differential distributions are also shown. Finally we briefly discuss indications from unpolarized experiments, that the heavy quark sector is not as well understood theoretically as we would like it to be for an extraction of $\Delta g$ using heavy quark processes. However, we conclude that if the experiments can determine the polarized and unpolarized cross sections separately, instead of only their ratio (the spin asymmetry), then it should be possible to keep the uncertainties under control. We finish the main part with a short summary in Chap. 9. The first appendix collects the remaining results for the virtual loops. Several important technical issues are discussed in App. B: series expansion of hypergeometric functions, (di)logarithmic branch cuts, $SU(N)$ color-factors, and two Slavnov-Taylor identities. The last appendix contains the lengthy virtual plus soft formulae.
Chapter 2

Preliminaries

2.1 Techniques for Polarized Calculations

As has been explained in the introduction, our main goal is the determination of the polarized gluon density $\Delta g$. To elucidate the definition of this object, let us examine the general expression for the polarized differential cross section of a process with a longitudinally polarized (point-like) photon and a longitudinally polarized nucleon in the initial state:

$$d\Delta\sigma_{\gamma N} \equiv \frac{1}{4} \left[ d\sigma_{\gamma N}^{++} + d\sigma_{\gamma N}^{--} - d\sigma_{\gamma N}^{-+} - d\sigma_{\gamma N}^{+-} \right].$$

(2.1)

Here a “+” or “-” as first index means that the spin of the photon is aligned or anti-aligned to its momentum (the photon has positive or negative helicity), respectively. Similarly the second index denotes the helicity of the nucleon. Note that the factor $1/4$ is a convention. If we had added all the cross sections in (2.1) indiscriminately, instead of subtracting those with mixed helicities, we would have obtained the unpolarized cross section $d\sigma_{\gamma N}$. The factor $1/4$ is required in the unpolarized case for the averaging over the helicities of the initial states. Experimentalists prefer measuring asymmetries defined by counting rates $N^{ij}$ as follows

$$A \equiv \frac{N^{++} + N^{--} - N^{-+} - N^{+-}}{N^{++} + N^{--} + N^{-+} + N^{+-}} \leq 1,$$

(2.2)

where we assume a common luminosity $N^{ij} = \mathcal{L}d\sigma^{ij}$. In the ratio some experimental uncertainties are expected to cancel, in particular it is not necessary to know the absolute normalization. However, for example acceptance corrections do usually not cancel and are often quite important. If we now wish to match the experimental definition with the simple theoretical form displayed in the second line of (2.2), we obviously have to introduce the factor $1/4$ in the polarized cross section as well.
2.1. Techniques for Polarized Calculations

Each of the $d\sigma^{ij}$ can be written in the following factorized form in QCD
\[
d\sigma^{ij}_{\gamma N} = \sum_{f=q,q\bar{q}} \int_0^1 dx \left[ d\sigma^{i+}_{\gamma f}(x K) f^+_i(x) + d\sigma^{i-}_{\gamma f}(x K) f^-_i(x) \right] \equiv d\sigma^{i+}_{\gamma f} \circ f^+_i + d\sigma^{i-}_{\gamma f} \circ f^-_i ,
\]
with $i, j = +, -$ and the functional dependence on other quantities than $x$ (in particular on the factorization scale $\mu_f$) is not shown for brevity. $d\sigma$ is the partonic cross section calculable in perturbative QCD. It depends on $x$ through $k = xK$, where $k$ is the momentum of the parton and $K$ is the momentum of the nucleon. Its second polarization index now corresponds to the parton $f$ involved. The upper polarization index of the parton $f$ corresponds to the nucleon and the lower one to the parton itself, e.g., $q^+$ would be the density of quarks with negative helicity in a nucleon with positive helicity. So we get
\[
d\Delta\sigma^{ij}_{\gamma N} = \frac{1}{4} \left[ d\sigma^{i+}_{\gamma f} \circ f^+_i + d\sigma^{i-}_{\gamma f} \circ f^-_i + d\sigma^{i+}_{\gamma f} \circ f^-_f + d\sigma^{i-}_{\gamma f} \circ f^+_f \right] - d\sigma^{i+}_{\gamma f} \circ f^-_f - d\sigma^{i-}_{\gamma f} \circ f^+_f - d\sigma^{i+}_{\gamma f} \circ f^-_f - d\sigma^{i-}_{\gamma f} \circ f^+_f
\]
\[\equiv d\Delta\sigma^{ij}_{\gamma f} \circ \Delta f ,
\]
\[\Delta f \equiv f^+_f - f^-_f \equiv f^+_f - f^-_f ,
\]
\[d\Delta\sigma^{ij}_{\gamma f} \equiv \frac{1}{2} \left[ d\sigma^{i+}_{\gamma f} - d\sigma^{i-}_{\gamma f} \right] .
\]
The important result used here is that parity $\mathbb{P}$ conservation of QCD guarantees for the partons and cross sections that
\[f^+_f = f^-_f \equiv f^+_f \quad \text{and} \quad f^+_f = f^-_f \equiv f^-_f ,
\]
\[d\sigma^{i+}_{\gamma f} = d\sigma^{i-}_{\gamma f} \quad \text{and} \quad d\sigma^{i+}_{\gamma f} = d\sigma^{i-}_{\gamma f} .
\]
Of course these simplifications would not occur when treating parity breaking processes for example of the electroweak sector. Note that due to parity we can introduce a single polarization index for the partons $f$ in (2.5) and (2.7), where now “$+$” or “$-$” mean the spin of the parton is aligned or anti-aligned with the spin of the nucleon, respectively.

We could of course repeat the same derivation for the unpolarized case by replacing all minus signs by plus signs. Furthermore it is obvious that the same conventions can be applied to the matrix elements, since the phase-space integration leading to the partonic cross sections can be factored out. Thus to collect our definitions that will be employed at the parton level, we have for a parton $f$ with $f = g, q, \overline{q}$
\[
\text{unpolarized:} \quad f(x, \mu_f^2) = f^+(x, \mu_f^2) + f^-(x, \mu_f^2) ,
\]
\[
\text{polarized:} \quad \Delta f(x, \mu_f^2) = f^+(x, \mu_f^2) - f^-(x, \mu_f^2) .
\]
where $f^+$ and $f^-$ are the densities with the parton spin aligned and anti-aligned to the spin of the nucleon, respectively. And for the matrix elements we get from (2.6)
\[
\text{unpolarized:} \quad |M|^2 = \frac{1}{2} \left[ |M|^2 (++) + |M|^2 (--) \right] ,
\]
polarized: \[ \Delta |M|^2 = \frac{1}{2} \left[ |M|^2 (++) - |M|^2 (-+) \right] , \quad (2.11) \]

where the polarization indices here denote the helicities of the incoming particles. The corresponding partonic differential cross sections \( d\sigma \) and \( d\Delta\sigma \) are obtained by phase-space integration over \( |M|^2 \) and \( \Delta |M|^2 \), respectively. There is one more somewhat sophisticated complication. As we have noted above, the unpolarized cross section is averaged over the helicities, i.e., for both the incoming photon and nucleon we have divided by a factor 2 for both possible helicities. But we will regularize the spurious singularities occurring in the higher order corrections by calculating in \( n = 4 + \varepsilon \) dimensions and only take the limit \( \varepsilon \rightarrow 0 \) when all singularities have canceled. A massless boson in \( n \) dimensions has \( n - 2 = 2(1 + \varepsilon/2) \), and not 2, spin degrees of freedom\(^1\). So we should divide by \( n - 2 \) and not by 2 when calculating in \( n = 4 + \varepsilon \) dimensions. We treat this issue by defining

\[
E_\varepsilon \equiv \begin{cases} 
1/(1 + \varepsilon/2) & \text{unpolarized} \\
1 & \text{polarized} 
\end{cases}, \quad (2.12)
\]

and adding the rule that the matrix elements have to be multiplied by a factor \( E_\varepsilon \) for each incoming boson. Note that \( E_\varepsilon = 1 \) for the polarized case, since the factor 1/4 occurring in (2.1) just conveniently keeps experimental and theoretical definitions on par in the “real world” of four dimensions.

As is obvious from (2.10) and (2.11), it would be of great practical advantage if one could obtain matrix elements for specified helicities. By calculating \( |M|^2 (++) \) and \( |M|^2 (-+) \) separately, we would gain both the polarized and unpolarized matrix elements simultaneously. Since the unpolarized processes under consideration in this work have already been calculated, we could then use the re-calculation of the unpolarized results as a check of our new polarized results! The needed helicity projection operators are well known, see e.g. [48], so for the incoming (anti)quarks with momentum \( p \), mass \( m \) and definite helicity \( h = \pm 1 \) we use

\[
u(p, h)\bar{\sigma}(p, h) = \frac{1}{2}(\gamma \cdot p + m)(1 - h\gamma_5) ,
\]

\[
u(p, h)\sigma(p, h) = \frac{1}{2}(\gamma \cdot p - m)(1 + h\gamma_5) .
\]

(2.13)

Note that we recover the usual unpolarized completeness relations when summing over \( h \). For outgoing (anti)quarks, where we have to sum over the unspecified helicities, we use the usual \( \sum_h u^* u = \gamma \cdot p + m \) and \( \sum_h v^* v = \gamma \cdot p - m \).

For a (real) incoming photon or gluon with momentum \( k \) and definite helicity \( \lambda \), we have

\[
\epsilon_\mu(k, \lambda)\epsilon^*_\nu(k, \lambda) = \frac{1}{2} \left[ -g_{\mu\nu} + \frac{k_\mu\eta_\nu + k_\nu\eta_\mu}{k \cdot \eta} + i\lambda\varepsilon_{\mu\nu\rho\sigma} \frac{k_\rho\eta_\sigma}{k \cdot \eta} \right] , \quad (2.14)
\]

\(^1\)A polarization vector has \( n \) components and satisfies two conditions: Lorentz \( k \cdot \epsilon = 0 \) and gauge freedom \( \epsilon_\mu \rightarrow \epsilon_\mu' = \epsilon_\mu + a k_\mu \).
where $\eta$ is an arbitrary light-like ($\eta^2 = 0$) four-vector with $k \cdot \eta \neq 0$. Upon summing over the helicities $\lambda$ we obtain the well-known physical polarization tensor $P_{\mu\nu}$. Thus when we sum over the unspecified helicities of outgoing photons or gluons, we employ

$$
\sum_\lambda \epsilon_\mu^* \epsilon_\nu^\lambda = P_{\mu\nu} = -g_{\mu\nu} + \frac{k_{\mu}n_{\nu} + k_{\nu}n_{\mu}}{k \cdot \eta}
$$

as the $\epsilon$-tensor term drops out. However, (2.14) introduces a lot of terms depending on the arbitrary vector $\eta$ into the calculation. It is of course a nice internal check of the calculation to see this dependence cancel out in the end, but since the intermediate terms are very lengthy, we have chosen to minimize the number of occurring terms.

$$
P_{\mu\nu} \mapsto \circ = -g_{\mu\nu} \mapsto \bullet + \frac{\eta_{\mu}k_{\nu}}{k \cdot \eta} + \frac{k_{\mu}n_{\nu}}{k \cdot \eta}
$$

![Figure 2.1: Graphical “rule” illustrating the replacement of the physical polarization sum $P_{\mu\nu}$ (\circ) by $-g_{\mu\nu}$ (\bullet) and appropriate ghost contributions (dashed lines). The minus signs in the lower half of the figure are due to the cut ghost loop.](image)

We will simply ignore the $(k^{\mu}\eta_{\nu} + k^{\nu}\eta_{\mu})/(k \cdot \eta)$ term, which will of course introduce unphysical polarizations. But they only contribute in graphs containing a triple-gluon vertex with two external gluons and we can eliminate these contributions by subtracting similar diagrams with two external ghosts, see Fig. 2.1 for illustration. Of course there is a trade-off: we got rid of all the “unpolarized” $\eta$-terms, but we need to calculate more diagrams. However, the number of triple-gluon graphs with two external gluons is small (one in the case of photoproduction), the ghost diagrams are easy to calculate and the cancellation of all the $\eta$-terms is implicit in the procedure. The graphical derivation shown in Fig. 2.1 is explained in more detail in [49, 50, 51]. Basically it exploits a Slavnov-Taylor identity derived in [52, 53], see also Sec. B.4. A further reduction of terms is achieved by setting the remaining $\eta$ in the $\epsilon$-tensor part of the polarization vector of an incoming particle to the momentum of the other incoming particle. Since we calculate with incoming partons, which are assumed to be on-shell and massless, the parton momenta $k_1$ and $k_2$ are light-like $k_1^2 = k_2^2 = 0$ and the scalar product $k_1 \cdot k_2 = s/2 \neq 0$, with $s$ being the non-zero center-of-mass energy squared. So the momenta can be used as choices for $\eta$. Since then all scalar products in matrix elements are written in terms of the process momenta only, cancellations occur in each of the matrix elements instead of just in the sum. So effectively we will use for a (real) incoming photon or gluon with momentum $k_1$ and definite helicity $\lambda_1$

$$
\epsilon_\mu(k_1, \lambda_1) \epsilon_\nu^*(k_1, \lambda_1) = \frac{1}{2} \left[ -g_{\mu\nu} + i\lambda_1 \epsilon_{\mu\nu\rho\sigma} \frac{k_1^\rho k_2^\sigma}{k_1 \cdot k_2} \right],
$$

(2.15)
where the other incoming particle has momentum \( k_2 \). For the outgoing photons or gluons we just use the metric \( \sum_{\lambda} \epsilon_{\mu \nu}^\lambda = -g_{\mu \nu} \).

Note that parity conservation implies that the terms with and without dependence on the helicity do not mix. That is for helicities \( \lambda_1 \) and \( \lambda_2 \): \( |M|^2 (\lambda_1, \lambda_2) = A + \lambda_1 B + \lambda_2 C + \lambda_1 \lambda_2 D \), with \( |M|^2 (++) = |M|^2 (-+) \) and \( |M|^2 (+-) = |M|^2 (-+) \) implies \( B = C = 0 \). Thus (2.10) and (2.11) directly yield

\[
|M|^2 (\lambda_1, \lambda_2) = |M|^2 + \lambda_1 \lambda_2 \Delta |M|^2.
\]  

(2.16)

So if we do not specify the two helicities of the incoming particles, be it boson or fermion, we can directly read off the polarized matrix element as the coefficient of the product of the helicities and the unpolarized matrix element as the rest. In practice we have used this to obtain both matrix elements directly.

Only one problem remains: The quantities \( \epsilon_{\mu \nu \rho \sigma} \) and \( \gamma_5 \) introduced by (2.15) and (2.13), respectively, are of purely four-dimensional nature and there exists no straightforward continuation to \( n \neq 4 \) dimensions. We treat them by applying the HVBM prescription [54], which provides an internally consistent extension of \( \epsilon_{\mu \nu \rho \sigma} \) and \( \gamma_5 \) to arbitrary dimensions. In this scheme the \( \epsilon \)-tensor continues to be a genuinely four-dimensional object and \( \gamma_5 \) is defined as in four dimensions, implying \( \{ \gamma^\mu, \gamma_5 \} = 0 \) for \( \mu = 0, 1, 2, 3 \), but \( \{ \gamma^\mu, \gamma_5 \} = 0 \) otherwise. This effectively splits the \( n \)-dimensional space into two subspaces, each one equipped with its own metric: one containing the four-space-time dimensions and one containing the remaining \( n - 4 \) dimensions, denoted “hat-space” henceforth. In the matrix elements we then encounter not only conventional \( n \)-dimensional scalar products of two momenta, like \( k \cdot p = g_{\mu \nu} k^\mu p^\nu \), which can be expressed in terms of the usual Mandelstam variables, but also similar scalar products in hat-space \( \hat{k} \cdot \hat{p} = g_{\mu \nu} \hat{k}^\mu \hat{p}^\nu \).

It would seem that this complicates the polarized calculation considerably, as we have additional hat space terms which require separate treatment in the phase-space integration. However, we are going to calculate one-particle-inclusive (1PI) cross sections. That is, we observe one of the outgoing particles, a heavy (anti)quark, while integrating over the rest of the outgoing particles. Any external observed momentum is inherently four-dimensional and thus has no hat space components. We of course also observe the incoming particles, so three momenta are directly set four-dimensional. Furthermore energy-momentum conservation implies that the sum of the other momenta is also four-dimensional. Incoming partons will carry a fraction of the momentum of their parents, thus the same applies for the partonic sub-processes. So in 1PI \( 2 \rightarrow 2 \) processes all momenta will be four-dimensional! Thus no hat contributions exist there. On the other hand in 1PI \( 2 \rightarrow 3 \) processes, where we cannot eliminate all hat components, we can obviously choose to work in the center-of-mass system of the two momenta that can have non-zero hat components. Then their hat components are opposite and equal \( \hat{p} = -\hat{k} \), and only one scalar hat product \( \hat{k}^2 \) occurs in the matrix elements and has to be taken care of in the phase-space integration. For this reason we just forget about hat space completely in this and the next chapter, which only treat \( 2 \rightarrow 2 \) processes. In Chap. 5 we will introduce the Gottfried-Jackson frame [55, 56], which introduces center-of-mass hat components, to
treat the $2 \to 3$ processes. There it is also shown, that almost all hat contributions are of $\mathcal{O}(\epsilon)$ and hence drop out when the limit $\epsilon \to 0$ is taken in the end. A final complication of the HVBM scheme [54] is the violation of the helicity conservation at the $qgq$-vertex, see [27] for a thorough discussion. However, this problem is easily treated by a finite scheme transformation during mass factorization, as is accordingly discussed in Chap. 6.

2.2 Born Cross Sections in $n = 4 + \epsilon$ Dimensions

![Feynman diagrams for the LO photon-gluon fusion process $\gamma g \to Q\bar{Q}$](image)

Figure 2.2: Feynman diagrams for the LO photon-gluon fusion process $\gamma g \to Q\bar{Q}$.

In this section we will re-calculate the well-known LO results for the unpolarized and polarized photo- and hadroproduction of heavy flavors. In our NLO calculations we will later encounter $1/\epsilon^2$ and $1/\epsilon$ poles, see Chap. 3 and Chap. 5, which will always multiply the corresponding Born results in some form. Naturally then the calculation of all finite parts, also in the removal of the infinities by renormalization (Chap. 4) and mass factorization (Chap. 6), requires the extension of the LO calculations up to $\mathcal{O}(\epsilon^2)$ in $n = 4 + \epsilon$ dimensions. In the following we derive the $2 \to 2$ phase-space integration and the squared matrix elements in $n$ dimensions, in order to obtain the $n$-dimensional Born cross section. Of course we can also take the $n \to 4$ limit of the results to extract the LO predictions themselves.

We start by calculating LO photoproduction, which just has the photon-gluon-fusion (PGF) diagrams depicted in Fig. 2.2. We use the following external momentum and color assignment (color is discussed in App. B.3)

\[
\gamma(k_1) + g^a(k_2) \to q_i(p_1) + \bar{q}_j(p_2),
\]

and the corresponding Mandelstam variables are given by

\[
s \equiv (k_1 + k_2)^2 = 2k_1 \cdot k_2, \\
t_1 \equiv t - m^2 = (k_2 - p_2)^2 - m^2 = -2k_2 \cdot p_2, \\
u_1 \equiv u - m^2 = (k_1 - p_2)^2 - m^2 = -2k_1 \cdot p_2, \\
k_1 + k_2 = p_1 + p_2 \quad \Rightarrow \quad s + t_1 + u_1 = 0.
\]
All the external lines are on-shell: $k_1^2 = k_2^2 = 0$ (real photon) and $p_1^2 = p_2^2 = m^2$, with $m$ denoting the heavy quark mass. All trace calculations in $n = 4 + \varepsilon$ dimensions are performed using the Mathematica [57] package Tracer [58].

In order to present the unpolarized and polarized results simultaneously in the most compact form, we will use henceforth $|\tilde{M}|^2$ to denote both the unpolarized $|\bar{M}|^2$ and polarized $\Delta |\tilde{M}|^2$ color-averaged squared matrix elements calculated according to (2.10) and (2.11), respectively. Similarly, in (2.20) below, $\hat{B}_{\text{QED}}$ denotes either the unpolarized $B_{\text{QED}}$ or the polarized $\Delta B_{\text{QED}}$ and we will use this kind of tilde notation for all occurring unpolarized and polarized pairs. The LO result for PGF can then be expressed as

$$|\tilde{M}|^2_{\text{LO}, g} = E_g^2 g^2 \varepsilon^2 \tilde{\varepsilon}_Q^2 \hat{B}_{\text{QED}},$$

$$\Delta B_{\text{QED}} = \left( \frac{t_1 + u_1}{u_1} + \frac{2m^2 s}{t_1 u_1} \right) \left( \frac{1 - m^2 s}{t_1 u_1} - 1 \right),$$

$$B_{\text{QED}} = \frac{t_1 + u_1}{u_1} + \frac{4m^2 s}{t_1 u_1} \left( 1 - \frac{m^2 s}{t_1 u_1} \right) + \varepsilon \left( \frac{s^2}{t_1 u_1} - 1 \right) + \varepsilon^2 \frac{s^2}{4t_1 u_1},$$

where $g$ and $\varepsilon$ are the strong and electromagnetic coupling constants, respectively, and $\varepsilon_Q$ is the electromagnetic charge of the heavy quark in units of $e$, e.g., $\varepsilon_Q = \varepsilon = 2/3$ for charm quarks. Notice that the polarized $\Delta B_{\text{QED}}$ retains its four-dimensional form and receives no $\mathcal{O}(\varepsilon)$ contributions, in contrast to the unpolarized $B_{\text{QED}}$. Furthermore the color-averaged color-factor\footnote{See App. B.3 for details on the calculation of SU(n) color-factors. In (2.20) the color-factor 1/2 is already included, i.e., the colorless matrix elements give $2E_g^2 g^2 \varepsilon^2 \tilde{\varepsilon}_Q^2 B_{\text{QED}}$.} for the squared matrix elements simply gives $\text{Tr} \left( T^a T^a \right) / (N^2_c - 1) = 1/2$, with the number of colors $N_c = 3$, so compared to the $\delta_{ii}$ of the $\gamma \gamma \rightarrow Q \bar{Q}$ process we find a characteristic factor $1/(2N_c)$. The name $\hat{B}_{\text{QED}}$ is hence motivated by the fact that we find the same function even in the pure QED process. We will see that it still appears when the remaining photon is also replaced by a gluon.

To obtain the $n$-dimensional cross section, we also need to perform the $2 \rightarrow 2$ phase-space integration in $n$ dimensions. Choosing the center-of-mass system (CMS) with $k_1 = \sqrt{s/4}(1, 0, 0, 1, 0)$ and $p_2 = (E_2, 0, [\vec{p}_2]|\sin \xi, [\vec{p}_2]|\cos \xi, 0)$, with all hat components zero as discussed in the previous section, we find

$$d\mathcal{P}_2 = \int \frac{d^n p_1}{(2\pi)^{n-1}} \frac{d^n p_2}{(2\pi)^{n-1}} \delta(p_1^2 - m^2) \Theta(E_1) \delta(p_2^2 - m^2) \Theta(E_2) (2\pi)^n \delta^{(n)}(k_1 + k_2 - p_1 - p_2)$$

$$= \frac{1}{(2\pi)^{n-2}} \delta(s + t_1 + u_1) \int d^n p_2 \delta(p_2^2 - m^2) \Theta(E_2)$$

$$= \frac{\pi^{\frac{n-1}{2}}}{(2\pi)^{n-2}} \frac{\Gamma(\frac{n}{2} - 1)}{\Gamma(\frac{n}{2})} \int dE_2 \Theta(E_2) \int d^3 \xi \sin^{n-3} \xi.$$ (2.22)

By transforming to invariant variables $(E_2, \xi) \rightarrow (t_1, u_1)$, we immediately get the standard $2 \rightarrow 2$ phase-space in $n = 4 + \varepsilon$ dimensions

$$d\mathcal{P}_2 = \frac{2\pi}{s} \delta(s + t_1 + u_1) \left[ (4\pi)^2 \frac{\pi}{s} \Gamma(1 + \frac{\varepsilon}{2}) \right]^{-1} \left( \frac{t_1 u_1 - m^2 s}{s} \right)^{\frac{\varepsilon}{2}} dt_1 du_1.$$ (2.23)
2.2. Born Cross Sections in \( n = 4 + \varepsilon \) Dimensions

Figure 2.3: Feynman diagrams for (a) the LO triple-gluon vertex contribution and (b) the corresponding ghost graphs according to Fig. 2.1 for the gluon-gluon fusion process \( gg \rightarrow Q\overline{Q} \).

Now one can write the \( n \)-dimensional \( 2 \rightarrow 2 \) cross section as

\[
\frac{d^2 \sigma_{2 \rightarrow 2}}{dt_i du_1} = F_\varepsilon \delta(s + t_1 + u_1) |\tilde{M}|^2 ,
\]

where \( F_\varepsilon \) collects all phase-space factors given in (2.23), the flux factor \( 1/2s \), and the mass parameter \( \mu \) is introduced to keep the gauge couplings \( g \) and \( \varepsilon \) dimensionless in \( n \) dimensions. \( \tilde{\sigma} \) denotes the unpolarized and polarized cross section \( \sigma \) and \( \Delta \sigma \), respectively. \( d\sigma_{g_i}^{(0)} \) can now be obtained from (2.24) by inserting the squared matrix elements of (2.20). If one is only interested in the Born result itself, one can of course perform the \( \varepsilon \to 0 \) limit in (2.20) and simply use \( F_\varepsilon = 1/(16\pi s^2) \). Our four-dimensional LO photoproduction results for \( \sigma_{g_i}^{(0)} \) and \( \Delta \sigma_{g_i}^{(0)} \) agree with those in [59, 64] and those derivable from [41, 60], respectively.

Next we will calculate the gluon-gluon cross section for LO hadroproduction. We replace in Fig. 2.2 the photon by a gluon and use the external momentum and color assignment

\[
g^a(k_1) + g^b(k_2) \rightarrow Q_i(p_1) + \overline{Q}_j(p_2) .
\]

Of course we now have to add the triple-gluon contribution of Fig. 2.3, which has the same external momenta and color and an internal gluon with the color index \( c \). To obtain incoming physical gluons, we subtract the incoming ghost contributions, shown in Fig. 2.3 (b), according to Fig. 2.1. Concerning the color-factors we now get two distinct contributions. After replacing the photon by a gluon in Fig. 2.2, the squared matrix element of graph (a) with (a) and (b) with (b) both have a (color-averaged) color-factor \( X = \text{Tr} \left\langle T^a T^b T^a T^b \right\rangle / (N_C^2 - 1)^2 \right\rangle = 2C_F /[4(N_C^2 - 1)] = 1/(4N_C) \right\rangle \), with \( C_F = (N_C^2 - 1)/(2N_C) \). However, the interference of these two graphs gives similarly \( \text{Tr} \left\langle T^a T^b T^a T^b \right\rangle / (N_C^2 - 1)^2 \right\rangle = X - Y \), with \( Y = C_A /[4(N_C^2 - 1)] \right\rangle \) and \( C_A = N_C \). The same color-factor \( Y \) multiplied with a (complex) number also appears on its own for the square of, and interference
with, the triple-gluon vertex diagram of Fig. 2.3 (and of course also for the ghost contributions), e.g., for the interference of Fig. 2.2 (a), $\gamma \to g$, with Fig. 2.3 (a) we obtain $\text{Tr} \left\langle T^a T^b T^c \right\rangle \left( \frac{g^4}{N_C^2} \right)^2 = i Y$. We see that for the color-factor $X$ we add the same “colorless” squared matrix elements with the same weight as in the photoproduction case, whereas for the color-factor $Y$ we collect the new non-abelian matrix elements and an abelian interference contribution. The result

$$|\tilde{M}_{LQg}^2| = E^2 g^4 \frac{1}{2(N_C^2 - 1)} \left[ 2C_F - C_A \frac{2t_1 u_1}{s^2} \right] \tilde{b}_{QED},$$

(2.27)

to be used with (2.21) and (2.24), then displays in the color-factor $X$ part the photoproduction result of (2.20) with strong couplings only and with the characteristic factor $1/(2N_C)$ for changing a photon to a gluon. On the other hand, the color-factor $Y$ part has different dynamics, as is evident by the additional factor $2t_1 u_1 / s^2$. This pattern of recovering “abelian” parts as coefficients for certain color-factors will repeat itself throughout the calculations. Our result (2.27) can be compared to [41, 44], see also [61, 49] for earlier work on the unpolarized hadroproduction of heavy quarks in LO.

**Figure 2.4:** The LO quark-antiquark annihilation process $q\bar{q} \to Q\bar{Q}$.

Finally, we will calculate the LO quark-antiquark annihilation process depicted in Fig. 2.4. The external momentum and color assignment is

$$\bar{q}_i(k_1) + q_i(k_2) \to Q_k(p_1) + \bar{Q}_k(p_2).$$

(2.28)

Here the color-factor is simply $\text{Tr} \left\langle T^a T^b \right\rangle \text{Tr} \left\langle T^a T^b \right\rangle / N_C^2 = C_F / (2N_C)$, where $a$ and $b$ are the color indices of the internal gluon in amplitude and complex conjugate amplitude, respectively. Then we get

$$|\tilde{M}_{LQ\bar{Q}}^2| = \frac{C_F}{N_C} g^4 \tilde{A}_{QED},$$

(2.29)

$$\Delta A_{QED} = \frac{t_1^2 + u_1^2}{s^2} - \frac{2m^2}{s} + \frac{\varepsilon}{2},$$

(2.30)

$$A_{QED} = \frac{t_1^2 + u_1^2}{s^2} + \frac{2m^2}{s} + \frac{\varepsilon}{2}.$$
2.2. Born Cross Sections in $n = 4 + \varepsilon$ Dimensions

![Graph showing LO asymmetry $A_c^{pp}$]  

**Figure 2.5:** Total LO charm spin asymmetry at RHIC [32] for $\sqrt{S} = 200, 500$ GeV (thick, thin lines) for different polarized parton sets [15, 18] and the unpolarized GRV'94 densities [62], plotted as function of $x_T^\text{min}$. This means varying the $p_T$-cut $p_T \geq p_T^\text{min}$, where $x_T^\text{min} = p_T^\text{min} / p_T^\text{max}$. For illustration the two $p_T^\text{min}$ values corresponding to $x_T^\text{min} = 0.02$ and $\sqrt{S} = 200$ and 500 GeV, respectively, are inserted. An estimate of $\pm \delta A_c^{pp}$ according to (2.31) is also shown.

$\delta_{\text{le}} / N_C^2 = 1$ and the electromagnetic instead of the strong coupling, hence the name $A_{QED}$. The unpolarized $n$-dimensional result agrees with the one in [46].

Note that helicity conservation at a (massless) quark-antiquark vertex requires that $|M|^2 (++) = 0$. Thus according to (2.10) and (2.11) we must have $\Delta |M|^2 = -|M|^2$. But we find from (2.30) that $\Delta |M|^2 + |M|^2 \sim \varepsilon \neq 0$. This is due to the commuting $\gamma_5$ in the $\varepsilon$-dimensional hat-space of the HVBM scheme [54]. However, this violation of helicity conservation only becomes relevant when $A_{QED}$ appears in front of NLO poles $1/\varepsilon$. For the pure LO process the limit $\varepsilon \to 0$ can be taken and helicity conservation is restored. In NLO, we have to subtract $\Delta A_{QED}$ of (2.30) in the mass factorization procedure of Chap. 6, if the NLO subprocesses are calculated in the HVBM scheme as well, as they are here. This corresponds to a finite scheme transformation and will help restoring helicity conservation. Only similar helicity violations due to $\Delta P_{qq}$ remain to be removed then, see Chap. 6 for details. It is for this reason that we quote the “unphysical” HVBM result for
the $\mathcal{O}(\varepsilon)$ of $\Delta A_{QED}$, instead of using $\Delta A_{QED} = -A_{QED}$. This completes our derivation of the LO matrix elements and cross sections for photoproduction and hadroproduction. The corresponding QED process with two gammas in the initial state can also be derived from the results shown here.

In the next chapters we will show how NLO corrections to these processes can be obtained. The theoretical motivation for doing so already has been given in the introduction. So we will here simply include a plot, Fig. 2.5, showing a LO prediction for the total charm hadroproduction asymmetry $A_{pp}^c = \Delta \sigma_{pp}^c / \sigma_{pp}^c$ at RHIC [32] for two different center-of-mass energies ($\sqrt{s} = 200$ GeV with $\mathcal{L} = 240$ pb$^{-1}$ as thick and $\sqrt{s} = 500$ GeV with $\mathcal{L} = 800$ pb$^{-1}$ as thin lines). A cut on minimal transverse momentum $p_T^\text{min}$ has been introduced, so the dependence on $x_T = p_T^\text{min} / p_T^\text{max}$, with the maximal kinematically allowed transverse momentum $p_T^\text{max} = \sqrt{S/4 - m_c^2}$ is shown. For details on deriving hadronic cross sections see Chap. 8. A rough statistical error estimate using the formula

$$\delta A_{pp}^c \simeq \frac{1}{P_2} \frac{1}{\varepsilon_2 \mathcal{L} \sigma_{pp}^c}$$  \hspace{1cm} (2.31)

with a detection efficiency of $\varepsilon = 0.001$ is also displayed. The distance between the lines for $\pm \delta A_{pp}^c$ is a crude estimate of the expected statistical error bars. By inspecting this plot, it is obvious that in LO this process, which will be measured soon at an experimental facility, allows a very good separation of different $\Delta g$ on the market [15, 18]. Hence the calculation of NLO corrections is needed also from a phenomenological point of view. Similar conclusions concerning (LO) photoproduction have already been drawn earlier, see for example [63].
Chapter 3

Virtual Contributions

3.1 Dimensional Regularization

Virtual contributions are characterized by the additional *internal* exchange of particles, so in NLO there is the same number of incoming and outgoing particles as in the Born diagrams. For the reactions considered here the virtual parts are $2 \rightarrow 2$ processes with the same simple kinematics (2.18) and phase-space (2.23) as the tree level diagrams. Since an internal line has to couple at its two endpoints, each of them yielding an additional factor $g$, only one additional internal line is allowed in NLO QCD, where we compute corrections of the order $\alpha_s \sim g^2$. Thus only three different topologies can arise as part of the amplitude, which are shown in Fig. 3.1.

![Diagram](image)

(a)  
(b)  
(c)

Figure 3.1: The topologies that can occur in the NLO virtual contributions: (a) self-energy, (b) vertex correction, and (c) box diagram. Note that the straight lines here can symbolize photons, gluons, ghosts, or quarks, as is appropriate.

The first type of diagram, Fig. 3.1 (a), is called self-energy, because the “same” particle appears at both (truncated) legs. It will also be denoted as bubble graph because of its shape and as 2-point function (2PF) graph, because it has two vertices. The second topology, Fig. 3.1 (b), is called vertex correction, because it results from an interaction between the legs of a vertex. It will also be named triangle or 3-point function (3PF) graph. Finally, Fig. 3.1 (c), is identified by its shape as box diagram or 4-point function (4PF) graph. Since the virtual diagrams contain the same number of external (observed) particles as the Born diagrams, the new matrix elements have to be added *coherently*. But since a single virtual amplitude already supplies the additional $\alpha_s$ of NLO, one only has to
consider the interference of the virtual with the tree level amplitudes when squaring the matrix elements. The products of the virtual diagrams with themselves can be discarded as being beyond NLO. Thus virtual contributions in general have simpler kinematics, phase-space and combinatorics than the real contributions, which will be considered in Chap. 5. However, in practice the virtual contributions can become quite numerous and are at least as difficult to compute as the real ones, because the additional particle exchange itself complicates the calculation considerably. In the following we will show step by step how to deal with the problems one encounters.

Since this additional particle is virtual and since energy-momentum conservation does not provide any constraint on it, its four-momentum can take on any value whatsoever and one has to integrate over all the possibilities. To illustrate the ensuing difficulties, we will consider a simplified integral first [64]. A massless virtual particle with four-momentum $q$ will introduce a $q^2$ in the denominator, so let us consider the integral

$$
\int \frac{d^4 q}{(-q^2)^\omega} \quad \text{with} \quad \omega = 1, 2, \ldots
$$

By inspecting the dimensions, we see that the integral is infrared (IR) divergent for $4 \leq 2\omega$ and ultraviolet (UV) divergent for $4 \geq 2\omega$. Thus it is divergent for all $\omega$. We regularize the integral by shifting the dimension of $q$ to $n = 4 + \varepsilon$. Obviously then $\varepsilon_{\text{IR}} > 2(\omega - 2)$ and $\varepsilon_{\text{UV}} < 2(\omega - 2)$ to obtain finite results. By performing a Wick rotation to the Euclidean momentum $Q^2 = q_0^2 + q_1^2 + q_2^2 + q_3^2$, integrating out the angles in a polar coordinate system and splitting the integral we obtain

$$
-i \frac{\Gamma(n/2)}{\pi^{n/2}} \int \frac{d^n q}{(-q^2)^\omega} = \int_0^{\Lambda^2} dQ^2 (Q^2)^{n/2-\omega-1} + \int_{\Lambda^2}^{\infty} dQ^2 (Q^2)^{n/2-\omega-1}
$$

$$
= 2\pi^{\varepsilon_{\text{IR}}-2(\omega-2)} \frac{\Gamma(n/2)}{\varepsilon_{\text{IR}}-2(\omega-2)} - 2\pi^{\varepsilon_{\text{UV}}-2(\omega-2)} \frac{\Gamma(n/2)}{\varepsilon_{\text{UV}}-2(\omega-2)}.
$$

For $\omega = 2$ one explicitly sees both the UV and IR pole. For other $\omega$ values we find as expected, that the first (IR regulated) term diverges in the UV limit $\Lambda \to \infty$ and the second (UV regulated) term diverges in the IR limit $\Lambda \to 0$.

Now we can on one hand choose to treat the UV and IR singularities separately, see for example [65]. Typically one would then first calculate the UV divergencies with $\varepsilon_{\text{UV}}$ while keeping the external legs off-shell. The latter provides the cutoff for the IR singularities which we introduced by hand in (3.2). Then one would remove the UV poles by renormalization, continue analytically $\varepsilon_{\text{UV}} \to \varepsilon_{\text{IR}}$ and put the external legs back on shell, exposing the IR poles which are later canceled against real contributions. This method has the advantage of clearly exhibiting the source of the poles, but leads to a rather tedious procedure. We can on the other hand decide to do without this distinction and immediately use analytical continuation to unify $\varepsilon_{\text{UV}} = \varepsilon_{\text{IR}} = \varepsilon$ with $\varepsilon > 0$. Then

---

1For more details on the used calculation techniques see App. A.1.
(3.2) appears in the simplest possible form

\[ \int \frac{d^n q}{(-q^2)^\omega} = 0, \quad (3.3) \]

and one can take here the \( n \to 4 \) limit immediately, since the integral now vanishes and thus no dependence on \( \varepsilon \) remains on the r.h.s. Note that our choice of setting \( \varepsilon_{\text{UV}} = \varepsilon_{\text{IR}} \) is well motivated by the fact, that in (3.2) the l.h.s. of the equation does not depend on a mass scale, whereas the r.h.s has two parts which do. Hence we should chose the continuation procedure in such a way, that the dependence on \( \Lambda \) cancels. All this does not mean that the divergencies have somehow magically disappeared in four dimensions. Rather we have made a special choice of evaluating the per se undetermined integral (3.1). This only makes sense if the end result of the complete calculation is finite and thus independent of the treatment of spurious divergencies in the intermediate steps, as it has to be for a physical process. We have chosen to use the unified \( \varepsilon \) approach throughout the calculations for simplicity.

### 3.2 Basic Scalar \( n \)-Point Functions

After having chosen our general method for dealing with the virtual corrections in the last section, we can now proceed to deal with the loop integrals that will actually appear in the calculation. The QCD propagators that can appear in the loops of Fig. 3.1 are shown in Fig. 3.2.

![Figure 3.2: Feynman Rules for the QCD propagators of (a) quark, (b) gluon and (c) ghost in the Feynman gauge. The \( i\epsilon \) shift in the denominators is omitted for brevity.](image)

Obviously in the denominator of the loop integrals, terms of the general form \( L_i \equiv l_i^2 - m_i^2 + i\epsilon \) will be appearing, where \( l_i \) is the four-momentum of the \( i \)-th propagating particle, \( m_i \) is its mass and the \( i\epsilon \)-prescription is used to ensure causality\(^2\). With respect to the loops in Fig. 3.1 one arbitrary propagator can be set to carry the loop momentum \( q \) only: \( l_1 = q \). Counting all external particles as incoming, at the next vertex the incoming four-momentum \( q_1 \) will be added into the loop and the next propagator has \( l_2 = q + q_1 \).

\(^2\)This causal \( \epsilon \) has nothing to do with the \( \epsilon \) of dimensional regularization.
Chapter 3. Virtual Contributions

and so forth. Thus we can define the following basic scalar integrals:

1PF: \[ A_0(m_1) \equiv \mu^{-\varepsilon} \int \frac{d^n q}{(2\pi)^n} \frac{1}{L_1}, \]

2PF: \[ B_0(q_1, m_1, m_2) \equiv \mu^{-\varepsilon} \int \frac{d^n q}{(2\pi)^n} \frac{1}{L_1 L_2}, \]  \hspace{1cm} (3.4)

3PF: \[ C_0(q_1, q_2, m_1, m_2, m_3) \equiv \mu^{-\varepsilon} \int \frac{d^n q}{(2\pi)^n} \frac{1}{L_1 L_2 L_3}, \]

4PF: \[ D_0(q_1, q_2, q_3, m_1, m_2, m_3, m_4) \equiv \mu^{-\varepsilon} \int \frac{d^n q}{(2\pi)^n} \frac{1}{L_1 L_2 L_3 L_4}. \]

We have added a 1-point function (1PF) \( A_0 \) for completeness. Furthermore the \( \mu^{-\varepsilon} \) with an arbitrary mass scale \( \mu \) in front guarantees for \( n = 4 + \varepsilon \) that the integral has an integer mass dimension\(^3\), i.e., \( [\mu^{-\varepsilon}][d^n q] = \text{mass}^{4-\varepsilon}\text{mass}^n = \text{mass}^4 \). Note that the virtual processes considered here are \( 2 \rightarrow 2 \), i.e., there are only four external momenta. Thus the 4PF diagrams must couple directly to those external momenta at NLO. We have defined the \( q_i \) to be incoming, so the momenta of the outgoing particles will enter with a negative sign. Thus energy-momentum conservation implies that \( q_4 = q + q_1 + q_2 + q_3 = q - q_4 \) here.

In App. A.1 it is shown that the integrals (3.4) can be brought into the general form

\[ A_0|_{j=1}, B_0|_{j=2}, C_0|_{j=3}, D_0|_{j=4} = iC_\varepsilon P_\varepsilon(j) \left( m^2 \right)^{2-j} \mathcal{J}_j K^{2-j+\frac{\varepsilon}{2}}, \]  \hspace{1cm} (3.5)

with \( j \) being the number of propagators, e.g., \( j = 3 \) for the 3PF \( C_0 \). In our processes the masses \( m_i \) in (3.4) are either zero (for light quarks, gluons or ghosts) or equal to the heavy quark mass \( m \), so this single mass scale has been factored out. We have introduced

\[ C_\varepsilon \equiv \frac{1}{16\pi^2 e^{\frac{\varepsilon}{2} (\gamma_E - 1 - 4\pi)}} \left( \frac{m^2}{\mu^2} \right)^{\frac{\varepsilon}{2}}, \quad S_l(n) \equiv \sum_{k=1}^{n} \frac{1}{k^l}, \]

\[ P_\varepsilon(j) \equiv (-1)^j \frac{(j-1) + \frac{\varepsilon}{2} \zeta(2) + S_l^2(j-1) - S_l(j-1)}{(j-2 - \frac{\varepsilon}{2})(j-1-\frac{\varepsilon}{2})} + \mathcal{O}(\varepsilon^3), \]  \hspace{1cm} (3.6)

and furthermore used Riemann \( \zeta(2) = \pi^2/6 \), Euler \( \gamma_E = 0.5772 \ldots \) and \( S_l(0) = 0 \). \( \mathcal{J}_j \) is a suitable Feynman parameter integration which is used to bring the denominator into the form \( (q^2 - K)^j \), e.g.,

\[ \mathcal{J}_1 = 1, \quad \mathcal{J}_2 = \int_0^1 dx, \quad \mathcal{J}_3 = 2 \int_0^1 dx dy x, \quad \mathcal{J}_4 = 6 \int_0^1 dx dy dz x^2 y. \]  \hspace{1cm} (3.7)

For \( j = 1, 2 \) the power of \( K \) is \( 2 - j + \frac{\varepsilon}{2} > 0 \), so the integration is finite and \( P_\varepsilon \) is only needed to \( \mathcal{O}(1) \). For \( j > 2 \) the power of \( K \) becomes negative and thus the integration can

\(^3\)This scale can also be viewed as keeping the regularized coupling dimensionless, see Chap. 4.
yield poles in $\varepsilon$. Examining Tab. 3.1, which collects the parametrization formulae, we see that poles can appear when there are terms of the type $x^{-1+\varepsilon/2}$ or $(1-x)^{-1+\varepsilon/2}$. This can happen for none, one or two parameters, so that we get finite, $1/\varepsilon$ or $1/\varepsilon^2$ contributions, respectively. Note that the integration over $z$ is always finite for the 4PF: if $K$ has a zero in $z$, it will be of the form $z^{-2+\varepsilon/2}$ or $(1-z)^{-2+\varepsilon/2}$ which can be integrated without leading to a pole. Thus even for the box integrals we get at most $1/\varepsilon^2$, which is of course expected, since the real contributions canceling the poles can not provide higher powers of $1/\varepsilon$ in NLO; simultaneous collinear and infrared limits in the emission of one gluon yields only $1/\varepsilon^2$.

Note also that the causal $\varepsilon-$prescription is important for determining the correct analytical continuation of the (di-)logarithms appearing in the calculation. Fortunately here we can drop all imaginary parts of the $\mathcal{J}_j$ integrals, which simplifies the continuation procedure. The reason is that they will be included in the virtual corrections, for which only the interference term with the Born amplitudes contributes at NLO, see the discussion in Sec. 3.1. That interference term can be written as $2\text{Re}[M_{\text{int}}M_{\text{Born}}^\dagger]$, so the imaginary parts of the virtual matrix element do not contribute, since the Born matrix element is real. For virtual NLO graphs one always has five extra $i$ from the Feynman rules as compared to the tree graphs. This together with the multiplication of $i\ldots$ in (3.5) gives a real prefactor multiplying the $\mathcal{J}_j$ Feynman parameter integrations. So we will need only the real parts of the Feynman parameter integrals, like for (3.11) and (3.14) below, which leads to a purely imaginary integral (3.15) below by multiplication with $i$ and then to a real contribution with the five $i$'s coming from the Feynman rules. For a discussion of some possible simplifications under these circumstances see App. B.2. Basically we can drop the causal $\varepsilon$ by treating logarithms with arguments on the branch cut appropriately, if we are only interested in the real parts.

![Figure 3.3: The hadroproduction box graph leading to the basic scalar integral (3.15).](image)

The needed set of basic scalar integrals has been collected in [44] and will be re-calculated in App. A.2. Here we will show how to perform the integration of the box integral $D_0(-k_1, p_1, p_2, 0, 0, m, 0)$ in some detail, to demonstrate the practical difficulties. It arises in the hadroproduction graph displayed in Fig. 3.3. By inserting the momenta in the expression of Tab. 3.1, we can write $K = a\hat{t} - b\hat{s} + \varepsilon^2$ with $\hat{t} \equiv -t_1/m^2$ and $\hat{s} \equiv s/m^2$, where we have used the fact that $a + b + c + d = 1$. Next we pick the parameters so that $K$ is linear in $z$, in order to facilitate the first integration. The choice $\{a, b, c, d\} = \{xy(1-z), xzy, x(1-y), 1-x\}$ satisfies this and upon integrating $K^{-2+\varepsilon/2}$ over $z$ and multiplying with $x^2y$ - see (3.7), the factor 6 cancels against the $1/6$ of $P_1(4)$.
Table 3.1: The factor $P_\varepsilon$ and the Feynman parametrized kernels of the basic $j$-point functions (3.4) used with (3.5) and (3.7). $P_\varepsilon$ is given up to the relevant order in $\varepsilon$. Note that $a + b + c + \ldots = 1$ and that the assignment of the shown sets can be in any order, i.e., there are $j!$ possibilities.

- we get the sum of two parts $I_{xy} + II_{xy}$:

$$
I_{xy} = \frac{2x^{-1+\varepsilon}(1-y)^{-1+\frac{1}{\varepsilon}}(1 + (\tilde{\ell} - 1)y)^{-1+\frac{1}{\varepsilon}}}{(-2 + \varepsilon)(\hat{s}(1-x) + tx(1-y))} \cdot \frac{2x^{\frac{1}{\varepsilon}} \left\{ -\hat{s}y + x [(1-y)^2 + \hat{s}y] \right\}^{1+\frac{1}{\varepsilon}}}{(-2 + \varepsilon)(\hat{s}(1-x) + tx(1-y))},
$$

$$
II_{xy} = \frac{2x^{\frac{1}{\varepsilon}} \left\{ -\hat{s}y + x [(1-y)^2 + \hat{s}y] \right\}^{1+\frac{1}{\varepsilon}}}{(-2 + \varepsilon)(\hat{s}(1-x) + tx(1-y))}.
$$

Beginning with part $I_{xy}$, we can perform the $x$-Integration, which leads to the hypergeometric function $_2F_1(1, \varepsilon, 1+\varepsilon, [\hat{s} - \tilde{\ell}(1-y)]/\hat{s})$, of which we take the series expansion, see (B.5) in App. B.1, to get:

$$
I_y = \frac{2(1-y)^{-1+\frac{1}{\varepsilon}}(1 + (\tilde{\ell} - 1)y)^{-1+\frac{1}{\varepsilon}}}{} \left[ 1 - \varepsilon \ln \left( \frac{\hat{s}(1-y)}{\hat{s}} \right) - \varepsilon^2 \text{Li}_2 \left( \frac{\varepsilon(1-y)}{\hat{s}} \right) \right],
$$

with the dilogarithmic function $\text{Li}_2(z)$. The remaining $y$ integration diverges for $y \to 1$ and is too complicated to be tackled directly. We define a counterterm which corresponds to the $y \to 1$ limit:

$$
I'_y = \frac{2(1-y)^{-1+\frac{1}{\varepsilon}}(1 + (\tilde{\ell} - 1)y)^{-1+\frac{1}{\varepsilon}}}{} \left[ 1 - \varepsilon \ln \left( \frac{\hat{s}(1-y)}{\hat{s}} \right) - \varepsilon^2 \frac{\pi^2}{6} \right].
$$

So $I_y - I'_y$ is finite with respect to the $y$ integration, which means that we can expand it in $\varepsilon$ to $O(1)$ before integrating! The resulting integral can be done. Furthermore $I'_y$ is simple enough to be integrated, keeping the $\varepsilon$ dependence, and expanding in $\varepsilon$ only after
the integration. It is important that (3.10) mirrors the complete \( y \to 1 \) structure, e.g., the \( \varepsilon^2 \) part cannot be dropped since it will contribute at \( \mathcal{O}(1) \), but will not occur in the integration of the \( \mathcal{O}(1) \) expansion of \( I_y - I_y^c \). The sum of both gives the result:

\[
I = -\frac{1}{\varepsilon t} \left\{ \frac{6}{\varepsilon^2} + \frac{3 + 2 \ln \tilde{s} + 2 \ln \tilde{t}}{\varepsilon} + \frac{3}{2} - \frac{\pi^2}{3} + \ln \tilde{t} \left( 1 - \ln \tilde{t} \right) + \ln \tilde{s} \left( 1 + 2 \ln \tilde{t} \right) \right\} . \quad (3.11)
\]

Turning to \( II_y \), we note that the integral only diverges when \( x \to 1 \). But \( x^{x^2} = 1 + \frac{x}{2} \ln x + \frac{x^2}{2} \ln^2 x + \ldots \), i.e., that term gives contributions other than unity only when multiplied by a pole in \( \varepsilon \). However, since the poles occur only for \( x = 1 \) where \( \ln(x - 1) = 0 \), we can simply set \( x^{x^2} \to 1 \) prior to integration. Then we can perform the \( x \) integration. The resulting hypergeometric functions are best transformed linearly, see for example [66], in order to exhibit the \( y \)-structure clearly. One gets:

\[
II_y = -\frac{4 i \pi \tilde{s}^{-1 + \frac{\varepsilon}{2}} \left( \tilde{s} - \tilde{t} (1 - y) \right)^{-\frac{\varepsilon}{2}} \left( 1 - y \right)^{-1 + \frac{\varepsilon}{2}} (1 + (\tilde{t} - 1)y)^{-1 + \frac{\varepsilon}{2}}}{2} \cdot 2 F_1 \left( \begin{array}{c} 1, \frac{\varepsilon}{2}, 1 + \frac{\varepsilon}{2} \\ \frac{i (\tilde{t} - (1 - (1 - \varepsilon)) (1 - y)) \pi}{i (1 - (1 - \varepsilon)) (1 - y)} \end{array} \right) + 4 (1 - y)^{-1 + \frac{\varepsilon}{2}} (1 - \tilde{y} y y)^{-1 + \frac{\varepsilon}{2}} \cdot \begin{array}{c} 2 \ F_1 \left( \begin{array}{c} 1, \frac{\varepsilon}{2}, 1 + \frac{\varepsilon}{2} \\ \frac{i (1 - (1 - \varepsilon)) (1 - y)}{1 + (\tilde{t} - 1) y} \end{array} \right) \end{array} \end{array} \\ \cdot \frac{(-2 + \varepsilon)}{2} \varepsilon \tilde{t} . \quad (3.12)
\]

The series expansion of the new hypergeometric function can also be found in App. B.1. Again we find a divergence in \( y \) and define an appropriate counterterm for the \( y \to 1 \) limit:

\[
II_y^c = -\frac{2 4 (1 - y)^{-1 + \varepsilon} + (1 - y)^{-1 + \frac{\varepsilon}{2}} \left[ -2 4 i \pi \varepsilon + (-1)^{\frac{\varepsilon}{2}} (24 + e^2 \pi^2) \right] \tilde{t} \tilde{y}^{\frac{\varepsilon}{2}}}{6 (-2 + \varepsilon) \varepsilon \varepsilon \tilde{t}} . \quad (3.13)
\]

Proceeding like for \( I_y \), we can complete the integration

\[
II = -\frac{1}{\varepsilon t} \left\{ \frac{2}{\varepsilon^2} + \frac{1 + 2 \ln \tilde{t}}{\varepsilon} + \frac{1 - \pi^2}{2} + 2 (1 + \ln \tilde{t}) \ln \tilde{t} \right\} . \quad (3.14)
\]

We have dropped any imaginary parts that occur in our final integrated results as mentioned above. Summing \( I + II \) and multiplying by \( i C_{\varepsilon \pi} \left( 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{8} \zeta(2) \right) \), we then get the final answer

\[
D_0(-k_1, p_1, p_2, 0, 0, m, 0) = \frac{i C_{\varepsilon \pi}}{s t l} \left\{ \frac{8}{\varepsilon^2} + 2 \left( 2 \ln \tilde{t} + \ln \tilde{s} \right) + 2 \ln \tilde{s} \ln \tilde{t} - 4 \zeta(2) \right\} , \quad (3.15)
\]
in accordance with Eqn. (A4) of [44].
3.3 Passarino-Veltman Decomposition

The fermion propagators of the virtual contributions Fig. 3.1 have the form $i\delta_{ij}(p + m)/(p^2 - m^2)$ and thus they introduce the loop momentum also in the numerator. We can generalize the basic definitions of (3.4) to take the more complicated numerator into account, e.g.,

$$D_{(q_0,q_{\mu_0},q_{\nu_0})}(q_1, q_2, q_3, m_1, m_2, m_3, m_4) \equiv \mu^{-n} \int \frac{d^n q}{(2\pi)^n} \frac{\{1, q_{\mu_0} q_{\nu_0} q_{\mu} q_{\nu} q_{\mu_0} q_{\nu_0} q_{\mu} q_{\nu}\}}{L_1 L_2 L_3 L_4}.$$  \hfill (3.16)

It is generally more difficult to calculate this type of tensor integral than the scalar integrals we have encountered up to this point. Note that for the processes we will be calculating tensors integrals of rank three or less have to be considered. A box diagram with four fermion propagators is of course possible, but it would require two outgoing photons or gluons, respectively, whereas we need here two outgoing heavy quarks. For this reason we do not have to examine integrals of the type $D_{\mu \nu \rho}$.

We know that the Lorentz covariant structure of the tensor loop integrals can only depend on the momenta of the attached legs and on the metric $g_{\mu \nu}$. This immediately suggests decomposing the integrals accordingly, a technique called Passarino-Veltman decomposition [47], which is also conveniently summarized in Ref. [67]. One can easily write down the possible Lorentz covariant combinations:

\begin{align*}
B^\mu &= q_1^\mu B_1, \\
B^{\mu \nu} &= q_1^\mu q_2^\nu B_{21} + g^{\mu \nu} B_{22}, \\
C^\mu &= q_1^\mu C_{11} + q_2^\mu C_{12}, \\
C^{\mu \nu} &= q_1^\mu q_1^\nu C_{21} + q_2^\mu q_2^\nu C_{22} + \{q_1 q_2\}^{\mu \nu} C_{23} + g^{\mu \nu} C_{24}, \\
C^{\mu \nu \rho} &= q_1^\mu q_2^\nu q_3^\rho C_{31} + q_1^\mu q_2^\nu q_2^\rho C_{32} + \{q_1 q_2 q_2\}^{\mu \nu \rho} C_{33} + \{q_1 q_2 q_2\}^{\mu \nu \rho} C_{34} \\
&\quad + \{q_1 g\}^{\mu \nu \rho} C_{35} + \{q_2 g\}^{\mu \nu \rho} C_{36}, \tag{3.17}
\end{align*}

\begin{align*}
D^\mu &= q_1^\mu D_{11} + q_2^\mu D_{12} + q_3^\mu D_{13}, \\
D^{\mu \nu} &= q_1^\mu q_1^\nu D_{21} + q_2^\mu q_2^\nu D_{22} + q_3^\mu q_3^\nu D_{23} + \{q_1 q_2\}^{\mu \nu} D_{24} + \{q_1 q_3\}^{\mu \nu} D_{25} \\
&\quad + \{q_2 q_3\}^{\mu \nu} D_{26} + g^{\mu \nu} D_{27}, \\
D^{\mu \nu \rho} &= q_1^\mu q_1^\nu q_1^\rho D_{31} + q_2^\mu q_2^\nu q_2^\rho D_{32} + q_3^\mu q_3^\nu q_3^\rho D_{33} + \{q_1 q_2 q_2\}^{\mu \nu \rho} D_{34} + \{q_1 q_3 q_3\}^{\mu \nu \rho} D_{35} \\
&\quad + \{q_2 q_3 q_3\}^{\mu \nu \rho} D_{36} + \{q_1 q_3 q_3\}^{\mu \nu \rho} D_{37} + \{q_2 q_3 q_3\}^{\mu \nu \rho} D_{38} + \{q_2 q_3 q_3\}^{\mu \nu \rho} D_{39} \\
&\quad + \{q_3 q_3 q_3\}^{\mu \nu \rho} D_{310} + \{q_1 g\}^{\mu \nu \rho} D_{311} + \{q_2 g\}^{\mu \nu \rho} D_{312} + \{q_3 g\}^{\mu \nu \rho} D_{313}.
\end{align*}

The scalar coefficient integrals on the r.h.s. can depend on all the possible scalar invariants of the leg momenta and on the masses $m_i$. The arguments of the tensor and scalar integrals have been omitted for brevity. The brackets $\{\ldots\}^{\mu \nu \rho}$ are a shorthand denoting the sum of all possible different Lorentz index permutations, for example $\{q_1 q_2 q_2\}^{\mu \nu \rho} = q_1^\mu q_2^\nu q_2^\rho + q_1^\nu q_1^\mu q_2^\rho + q_2^\mu q_2^\nu q_1^\rho$.
\[ q_1^\alpha q_2^\beta q_3^\gamma + q_1^\beta q_2^\gamma q_3^\alpha \] and \( \{ q_1, q \}^{\mu \nu} = q_1^\mu q_2^\nu + q_1^\nu q_2^\mu + q_1^\alpha q_2^\gamma \). All Lorentz index permutations must have the same scalar integral as coefficient, since the tensor integrals like \((3.16)\) stay invariant under these permutations. This property will later be shown to result in stringent consistency checks on the decomposition, since the same coefficient will be obtained no matter how the projection is ordered.

The decomposition, a \(13 \times 13\) matrix problem in case of \( D^\mu \nu \), looks forbidding, but it is possible to reduce it to at most a \(3 \times 3\) matrix problem by taking into account the fact that leg momenta are added one by one into the loop. As already mentioned above, in the propagators \( L_i \equiv \frac{p^2}{m_i^2 + i \epsilon} \) the momentum \( p \) has then the simple progressions

\[ l_1 = q, \ l_2 = q + q_1, \ l_3 = q + q_1 + q_2 \text{ and } l_4 = q + q_1 + q_2 + q_3. \]

Thus we can rewrite the scalar product of the leg momenta and the loop momentum in the following way

\[ q_1 \cdot q = (L_2 - L_1 + f_1)/2 \quad \text{with} \quad f_1 \equiv m_2^2 - m_1^2 - q_1^2, \]
\[ q_2 \cdot q = (L_3 - L_2 + f_2)/2 \quad \text{with} \quad f_2 \equiv m_3^2 - m_2^2 - (q_1 + q_2)^2 + q_1^2, \]
\[ q_3 \cdot q = (L_4 - L_3 + f_3)/2 \quad \text{with} \quad f_3 \equiv m_4^2 - m_3^2 - (q_1 + q_2 + q_3)^2 + (q_1 + q_2)^2. \]

Since the \( L_i \) terms introduced by rewriting the scalar product will cancel against the propagators in the denominator and since the \( f_i \) do not contain the loop momentum, we can effectively remove \( q \) from the numerator this way! The price to be paid is the introduction of new scalar integrals of the form occurring for loops with one propagator less. To make this clear, consider as an example

\[
q_2^\mu D_\mu = \mu^{-\epsilon} \int \frac{d^n q}{(2\pi)^n} \frac{q_2 \cdot q}{L_1 L_2 L_3 L_4} = \int \frac{(L_3 - L_2 + f_2)/2}{L_1 L_2 L_3 L_4} \]

\[ = \frac{1}{2} \left[ \int \frac{1}{L_1 L_2 L_4} - \int \frac{1}{L_1 L_3 L_4} + f_2 D_0 \right] C_6(1, 2, 4) \quad C_6(1, 3, 4) \]

(3.19)

where the integration sign is a shorthand for \( \mu^{-\epsilon} \int d^n q/(2\pi)^n \) here and below.

Apart from the expected scalar integral \( D_0 \) corresponding to the tensor integral \( D_\mu \), one has two new scalar integrals \( C_6(1, 2, 4) \) and \( C_6(1, 3, 4) \) having three propagator terms in the denominator, which however differ from those of the generic \( C_6 = C_6(1, 2, 3) \) introduced directly by the vertex corrections. But now all we have to do is to project onto these scalar products of loop and leg momenta, which at worst for the boxes is a \(3 \times 3\) matrix problem, and calculate the (new) scalar integrals. To this end one defines a projective momentum

\[ P_1^\mu q_{l\mu} = \delta_{il}, \]

(3.20)

where the indices \( i, l = 1, 2, \ldots, d \) run over the number of independent leg momenta \( d \), that is the number of propagators in the loop minus one. For self-energies \( B \) we have only one independent leg momentum and thus

\[ P_1^\mu = X_B^{-1} q_1^\mu \quad \text{with} \quad X_B = q_1^2. \]

(3.21)
For vertex corrections $C$ there are two independent leg momenta and so

\[
\begin{pmatrix}
F_1^\mu \\
F_2^\mu \\
F_3^\mu
\end{pmatrix} = X_C^{-1}
\begin{pmatrix}
q_1^\mu \\
q_2^\mu \\
q_3^\mu
\end{pmatrix}
\quad \text{with} \quad X_C = \begin{pmatrix}
q_1^2 & q_1 \cdot q_2 \\
q_1 \cdot q_2 & q_2^2
\end{pmatrix}.
\]

(3.22)

Finally for box integrals there are three

\[
\begin{pmatrix}
P_1^\mu \\
P_2^\mu \\
P_3^\mu
\end{pmatrix} = X_D^{-1}
\begin{pmatrix}
q_1^\mu \\
q_2^\mu \\
q_3^\mu
\end{pmatrix}
\quad \text{with} \quad X_D = \begin{pmatrix}
q_1^2 & q_1 \cdot q_2 & q_1 \cdot q_3 \\
q_1 \cdot q_2 & q_2^2 & q_2 \cdot q_3 \\
q_1 \cdot q_3 & q_2 \cdot q_3 & q_3^2
\end{pmatrix}.
\]

(3.23)

Only when the inverse of the matrices $X$ exists can this simplification be used.

Using these definitions we can already treat all the vector integrals occurring in the $n$PF graphs. As an example $C^\mu = q_1^\mu C_{11} + q_2^\mu C_{12}$ will be worked out explicitly here:

\[
\begin{pmatrix}
C_{11} \\
C_{12}
\end{pmatrix} = \begin{pmatrix}
P_1^\mu \\
P_2^\mu
\end{pmatrix} C_{\mu} = X_C^{-1}
\begin{pmatrix}
q_1^\mu C_{\mu} \\
q_2^\mu C_{\mu}
\end{pmatrix} \equiv X_C^{-1}
\begin{pmatrix}
R_1 \\
R_2
\end{pmatrix},
\]

(3.24)

with

\[ R_1 = \frac{1}{2} \left[ B_0(1, 3) - B_0(2, 3) + f_1 C_0 \right], \quad R_2 = \frac{1}{2} \left[ B_0(1, 2) - B_0(1, 3) + f_2 C_0 \right], \]

(3.25)

and the inverse of $X_C$ is easily calculated to be

\[
X_C^{-1} = \frac{1}{q_1^2 - (q_1 \cdot q_2)^2} \begin{pmatrix}
q_2^2 & -q_1 \cdot q_2 \\
-q_1 \cdot q_2 & q_1^2
\end{pmatrix}.
\]

(3.26)

Note that for the calculation of $B_0(2, 3)$, we can shift the integration $q + q_1 \to q$

\[
B_0(2, 3) = \int \frac{1}{\left[ (q + q_1)^2 - m_2^2 \right] \left[ (q + q_1 + q_2)^2 - m_3^2 \right]} = \int \frac{1}{\left[ (q^2 - m_2^2) \left[ (q + q_2)^2 - m_3^2 \right] \right]},
\]

(3.27)

brining it into the standard form for $B_0$. Similarly one proceeds for $C_0(2, 3, 4)$.

Next we need to construct a projective tensor which singles out the metric $g_{\mu\nu}$, using the projective momentum $P_1^\mu$,

\[
P^{\mu\nu} = \frac{1}{n - d} \left[ g^{\mu\nu} - \sum_{l=1}^{d} P_l^\mu q_{l\nu} \right],
\]

(3.28)
where \( d \) again is the number of independent leg momenta and \( n = 4 + \varepsilon \) is the spacetime dimension. This leads to the desired properties

\[
P^\mu_\nu q_{\mu} = P^\mu_\nu q_{\nu} = 0, \quad P^\mu_\nu g_{\mu\nu} = 1. \tag{3.29}
\]

As an example, the 3PF coefficient of the metric is obtained using this projective tensor:

\[
C_{24} = P^\mu_\nu C_{\mu\nu} = \frac{1}{n-2} \left[ \left( d^\mu_\nu - P^\mu_1 q^\nu_1 - P^\mu_2 q^\nu_2 \right) \int \frac{q_{\mu} q_{\nu}}{L_1 L_2 L_3} \right] = \frac{1}{n-2} \left[ \int \frac{1}{L_2 L_3} + m_i^2 \int \frac{1}{L_1 L_2 L_3} - R_3 - R_6 \right] = \frac{1}{n-2} \left[ m_i^2 C_0 - \frac{1}{2} \left( f_1 C_{11} + f_2 C_{12} - B_0(2, 3) \right) \right], \tag{3.30}
\]

\[
R_3 = \frac{1}{2} P^\mu_1 \int \left[ \frac{q_{\mu}}{L_1 L_3} - \frac{q_{\mu}}{L_2 L_3} + f_1 \frac{q_{\mu}}{L_1 L_2 L_3} \right] = \frac{1}{2} \left( B_1(1, 3) - B_0(2, 3) + f_1 C_{11} \right) \tag{3.31},
\]

\[
R_6 = \frac{1}{2} P^\mu_2 \int \left[ - \frac{q_{\mu}}{L_1 L_3} - \frac{q_{\mu}}{L_2 L_3} - f_2 \frac{q_{\mu}}{L_1 L_2 L_3} \right] = \frac{1}{2} \left[ - B_1(1, 3) + f_2 C_{12} \right]. \tag{3.32}
\]

In the first step \( q^2 = L_1 + m_i^2 \) and (3.18) were used. Note the shift \( q \to q + q_1 \) in the second integration in the first step of calculating \( R_3 \), so that \( B_\mu(2, 3) = q_{2\mu} B_1(2, 3) \), which gives no contribution when contracted with \( P^\mu_1 \). It is of great advantage that this type of projection properties can be used on the tensors with reduced rank\(^4\) in the intermediate steps.

Turning to the \( C_{\mu\nu} \) coefficients depending on the leg momenta, we can use the projective momentum twice

\[
\begin{pmatrix}
C_{21} \\
C_{23}
\end{pmatrix} = P_1^\mu \begin{pmatrix}
P_1^\mu \\
P_2^\mu
\end{pmatrix} \tilde{C}_{\mu\nu} = X_C^{-1} \begin{pmatrix}
R_3 - C_{24} \\
R_4
\end{pmatrix}, \tag{3.33}
\]

\[
\begin{pmatrix}
C_{23} \\
C_{22}
\end{pmatrix} = P_2^\mu \begin{pmatrix}
P_1^\mu \\
P_2^\mu
\end{pmatrix} \tilde{C}_{\mu\nu} = X_C^{-1} \begin{pmatrix}
R_5 \\
R_6 - C_{24}
\end{pmatrix},
\]

\[
R_4 \equiv P_1^\mu q_2^\nu C_{\mu\nu} = \frac{1}{2} \left[ B_1(1, 2) - B_1(1, 3) + f_2 C_{11} \right], \tag{3.34}
\]

\[
R_5 \equiv P_2^\mu q_1^\nu C_{\mu\nu} = \frac{1}{2} \left[ B_1(1, 3) - B_1(2, 3) + f_1 C_{12} \right],
\]

\(^4\)For \( P^\mu_1 B_{\mu\nu} \) one needs \( P^\mu_1 \int q_{\mu}/L_1 \to 0 \), easily proven in the rest frame of \( q_1 \), because then \( q_1 \cdot q = q_1^0 q_0 \) yields an integral odd in the energy component \( q_0 \).
where $\tilde{C}_{\mu \nu} \equiv C_{\mu \nu} - g_{\mu \nu} C_{35}$ has the metric contribution subtracted. Since there are two ways of projecting out $C_{35}$, depending on whether $P_1$ or $P_2$ is used first, this coefficient is obtained twice. This kind of redundancy occurs for all possible permutations of the projection order and allows one to perform internal consistency checks for all the multiply obtained coefficients!

For $C_{\mu \nu \rho}$, we already know how to project out the terms with the metric, e.g.,

$$
\begin{pmatrix}
C_{35} \\
C_{36}
\end{pmatrix} = P^{\mu \omega}
\begin{pmatrix}
P_1^\rho \\
P_2^\rho
\end{pmatrix} C_{\mu \nu \rho} = X^{-1}_C
\begin{pmatrix}
R_{10} \\
R_{11}
\end{pmatrix},
$$

(3.35)

$$
R_{10} \equiv P^{\mu \omega} q_1^\rho C_{\mu \nu \rho} = \frac{1}{2} [B_{22}(1, 3) - B_{22}(2, 3) + f_1 C_{21}] ,
$$

(3.36)

$$
R_{11} \equiv P^{\mu \omega} q_2^\rho C_{\mu \nu \rho} = \frac{1}{2} [B_{22}(1, 2) - B_{22}(1, 3) + f_2 C_{21}] .
$$

It is convenient to construct a complementary tensor to $P^{\mu \omega}$, which projects onto specific combinations of two leg momenta:

$$
P_{kl}^{\mu \omega} \equiv P_k^\mu P_l^\omega - (P_k \cdot P_l) P^{\mu \omega} ,
$$

(3.37)

with the properties

$$
P_{kl}^{\mu \omega} q_{ij} q_{j \nu} = \delta_{ik} \delta_{jl} , \quad P_{kl}^{\mu \omega} g_{\mu \nu} = 0 .
$$

(3.38)

Then we can for example write

$$
\begin{pmatrix}
C_{31} \\
C_{32}
\end{pmatrix} = P_{11}^{\mu \omega}
\begin{pmatrix}
P^\rho_1 \\
P^\rho_2
\end{pmatrix} \tilde{C}_{\mu \nu \rho} = X^{-1}_C
\begin{pmatrix}
R_{12} - 2 C_{35} \\
R_{13}
\end{pmatrix},
$$

(3.39)

$$
R_{12} \equiv P_{11}^{\mu \omega} q_1^\rho C_{\mu \nu \rho} = \frac{1}{2} [B_{21}(1, 3) - B_{0}(2, 3) + f_1 C_{21}] ,
$$

(3.40)

$$
R_{13} \equiv P_{11}^{\mu \omega} q_2^\rho C_{\mu \nu \rho} = \frac{1}{2} [B_{21}(1, 2) - B_{21}(1, 3) + f_2 C_{21}] ,
$$

where $\tilde{C}_{\mu \nu \rho} \equiv C_{\mu \nu \rho} - \{q_1 g\}_{\mu \nu \rho} C_{35}$ has the metric part contributing here subtracted.

This completes the necessary collection of projection operators. We have already performed part of the necessary decompositions for the vertex corrections in the examples given above, and the self-energy and box integrations can be treated likewise. A collection of further results can be found in App. A.3. Though this procedure is straightforward, its actual implementation requires a computer algebra system like Mathematica. The general decomposition for arbitrary momenta and masses of the 4PF alone results in Mathematica output of more than three MByte length before simplification. Managing this lengthy result was facilitated by defining a space in the possible basic functions $B_0$, $C_0$ and $D_0$, so that the coefficient relations become vector equations in that space. Simplifying the formulae for specific momenta and inserting the basic functions will usually reduce the length of the 4PF formulae by two orders of magnitude.
3.4 Some Final Remarks

Upon calculating the actual virtual processes using the formalism of Sec. 3.3 and App. A.3, one will need numerous scalar integrals which do not seem to be included in the basic set of App. A.2. But those integrals can always be brought into a form where they are either seen to be directly equal to one of the basic integrals or derivable by simple manipulations. There are several “physical” ways to arrive at such transformations. Many of them can be obtained by simple crossing. For example the integral \( B_0(p_1 - k_2, 0, m) \) obviously is obtained from the known integral \( B_0(p_1 - k_1, 0, m) \) by crossing \( k_1 \leftrightarrow k_2 \). To this end we can simply replace \( t, t_1 \to u, u_1 \) in the known result (A.20). Also one often obtains integrals which just correspond to assigning the loop momentum in a different way, see Fig. 3.4 for the simple case of 2PFs. Similarly we can derive for 3PFs that

\[
C_0(p_1, p_2, m_1, m_2, m_3) = C_0(-p_1, -p_2, m_1, m_2, m_3) = C_0(p_1 + p_2, -p_1, m_1, m_2, m_3) = C_0(p_2, p_1, m_2, m_1, m_3) = C_0(p_2, p_1, m_3, m_2, m_1)
\]

by reassigning the loop momentum and of course we can also treat the 4PF \( D_6 \)'s this way.

![Figure 3.4](image)

**Figure 3.4:** By assigning the loop momentum differently in one graph, it is shown that \( B_0(p_1, m_1, m_2) = B_0(-p_1, m_1, m_2) = B_0(p_1, m_2, m_1) \).

One can also simply shift the loop momentum, which does not change the value of the integral. For example setting \( q \to q + p_2 \) in \( C_0(p_1, -k_1 - k_2, 0, m, m) \) yields the integral \( C_0(p_2, p_1, m, 0, m) \), proving their equality. But in practice it is much simpler to just insert the momenta in the kernels \( K \) of Tab. 3.1 and compare to those of the standard set. For instance in the example above, \( C_0(p_1, -k_1 - k_2, 0, m, m) \) gives \( K = -be \frac{m}{m^2} + (1-a)^2 \). But we know that the basic integral \( C_0(p_2, p_1, m, 0, m) \), see (A.24), leads to \( K = -ac \frac{m}{m^2} + (1-b)^2 \), so since the assignment of the parameters \( a, b, c \) is arbitrary, both integrals are equal. Also equalities due to the reassignment of the loop momentum are immediately obvious. Taking the case covered in Fig. 3.4, one always obtains \( K = -ab + am_1^2 + bm_2^2 \), switching \( a \leftrightarrow b \) if needed. Furthermore changes of the kinematic variables due to crossing are trivial, e.g., \( B_0(p_1 - k_2, 0, m) \) leads to \( K = -ab \frac{m}{m^2} + b \) and \( B_0(p_1 - k_1, 0, m) \) gives \( K = -ab \frac{m}{m^2} + b \). Also equalities like \( C_0(p_1 - k_1, -k_2, 0, m, m) = C_0(p_1, -k_1, 0, m, m) \), which need some work to be proven otherwise, are obtained by just writing down the kernels. With this method it is an easy exercise to obtain the needed relations between integrals, about 40 were needed in our calculation.

A special simplification can be used when working on the QED-like box integrals. Since we calculate \( 2 \to 2 \) processes, there are only three independent momenta, the fourth can be calculated using energy-momentum conservation \(-q_4 = q_1 + q_2 + q_3\), counting all
momenta as incoming. Taking a look at the propagators in $D_0$ in (3.4), we can write

\[
\begin{align*}
q^2 - m_1^2 + i\epsilon &= (q + q_1)^2 - m_2^2 + i\epsilon \\
(q + q_1 + q_2)^2 - m_3^2 + i\epsilon &= (q + q_1 + q_2 + q_3)^2 - m_4^2 + i\epsilon
\end{align*}
\Rightarrow
\begin{align*}
(q - q_1 - q_2 - q_3)^2 - m_2^2 + i\epsilon &= (q - q_1 - q_3)^2 - m_3^2 + i\epsilon \\
(q - q_1)^2 - m_4^2 + i\epsilon
\end{align*}
\]

(3.41)

Simply by replacing $q \rightarrow -q$ in the integration\(^5\) we then obtain the relation

\[D_0(q_1, q_2, q_3, m_1, m_2, m_3, m_4) = D_0(q_1, q_2, q_3, m_1, m_4, m_2, m_3) \overset{\text{abbr.}}{\rightarrow} D_0 = \overline{D}_0.\tag{3.42}\]

We can also show this by inserting the momenta into the kernel $K$ given in Tab. 3.1. $\overline{D}_0$ leads to the same kernel as $D_0$ upon switching the assignment $b \leftrightarrow d$. In the tensor integrals the $q \rightarrow -q$ shift adds a minus for every loop momentum, so using the same abbreviation as in (3.42), we can write

\[
D^\mu = -\overline{D}^\nu, \quad D^\mu\nu = \overline{D}^{\nu\rho}, \quad D^\mu\nu\rho = -\overline{D}^{\nu\rho}.\tag{3.43}
\]

Now we can insert this in the tensor decomposition (3.17), for example

\[
\begin{align*}
D^\mu &= q_1^\mu D_{11} + q_2^\mu D_{12} + q_3^\mu D_{13} \\
&= -\overline{D}^\nu = -(q_1^\nu \overline{D}_{11} + q_2^\nu \overline{D}_{12} + q_3^\nu \overline{D}_{13}) \\
&= q_1^\nu \overline{D}_{11} + q_2^\nu (\overline{D}_{11} - \overline{D}_{13}) + q_3^\nu (\overline{D}_{11} - \overline{D}_{12}) \\
\Rightarrow
D_{11} &= \overline{D}_{11}, \quad D_{12} = \overline{D}_{11} - \overline{D}_{13}, \quad D_{13} = \overline{D}_{11} - \overline{D}_{12}.\tag{3.44}
\end{align*}
\]

Similar relations can be derived for the other tensor coefficients.

Figure 3.5: For this QED-like box graph a simplified tensor decomposition (3.47) is possible.

By itself this is not very helpful, except as a further method for checking the decomposition. But in the QED-like box Fig. 3.5, we get for $D \rightarrow D(p_1, -k_1, -k_2, 0, m, m, m)$ and $\overline{D} \rightarrow D(p_2, -k_2, -k_1, 0, m, m, m)$ exactly the same projection coefficients. This can be easily checked by noting that the matrix $X_D$ of the projective momenta in (3.23) and

\(^5\)For every of the $n$ components the minus in the measure is compensated by the minus in the integration limits, effectively only the kernel changes.
the \( f_i \) collected in (3.18) are the same in both cases. The new scalar integrals obtained by the projection will also be the same, since the second and fourth propagator, \( L_2 \) and \( L_4 \), which are interchanged in \( D \leftrightarrow \overline{D} \), have on one hand the same mass and on the other hand the same square of the sum of external \( q_i \). As an explicit example compare \( C_6(1, 3, 4) \) with \( \overline{C_6}(1, 3, 4) \). Both have the same masses \( m_i \) and inserting \( q_1 = p_1 - k_1, \ q_2 = -k_2 \) and \( q_1 = p_2 - k_2, \ q_2 = -k_1 \), respectively, in the \( K \) found in Tab. 3.1 will yield the same kernel. A different way of coming to this conclusion is noting that (A.3) introduces Feynman parameters to a numerator with loop four momenta \( q^\mu q'^\nu \ldots \), so that for the tensor integrals the assignment of \( a, b, c, d \) changes the result obtained for the projection coefficients. But in the QED-like integral here the switch \( b \leftrightarrow d \) mentioned below (3.42) is not necessary: the propagators already lead to the same \( K \), because of the similarity between \( L_2 \) and \( L_4 \). So the projection coefficients will be equal. At any rate, we can set \( D_{ij} = \overline{D}_{ij} \) here! Then of course the relations like in (3.44) can be used to eliminate dependent scalar coefficients. One finds eight relations:

\[
D_{11} = D_{12} + D_{13}, \quad D_{24} = (D_{21} + D_{22} - D_{23})/2, \\
D_{25} = (D_{21} - D_{22} + D_{23})/2, \quad D_{31} = -2D_{32} - 2D_{33} + 3D_{36} + 3D_{37}, \\
D_{34} = -D_{32} - D_{33} + 2D_{36} + D_{37}, \quad D_{35} = -D_{32} - D_{33} + D_{36} + 2D_{37}, \\
D_{310} = (-D_{32} - D_{33} + D_{36} + D_{37} + D_{38} + D_{39})/2, \quad D_{311} = D_{312} + D_{313}.
\] (3.45)

We can now write the Lorentz structure of \( D(p_1, -k_1, -k_2, 0, m, m, m) \) in a neat way, using the following further redefinitions:

\[
\hat{D}_{21} = -\frac{1}{2}(D_{21} - D_{22} - D_{23}), \quad \hat{D}_{30} = \frac{1}{2}(D_{32} - D_{33}), \\
\hat{D}_{37} = \frac{1}{2}(D_{33} - D_{37}), \quad \hat{D}_{38} = \frac{1}{2}D_{38}, \quad \hat{D}_{39} = \frac{1}{2}D_{39}.
\] (3.46)

The final simplified result is then

\[
D^\mu = t^\mu D_{12} + u^\nu D_{13},
\]

\[
D^{\mu\nu} = \left\{p_1 p_2\right\}^{\mu\nu} \hat{D}_{21} + t^\mu t^\nu D_{22} + u^\mu u^\nu D_{23} + \left\{k_1 k_2\right\}^{\mu\nu} D_{26} + g^{\mu\nu} D_{27},
\]

\[
D^{\mu\nu\rho} = t^\mu t^\nu t^\rho D_{32} + u^\mu u^\nu u^\rho D_{33} + \left\{t p_1 p_2\right\}^{\mu\nu\rho} \hat{D}_{36} + \left\{u p_1 p_2\right\}^{\mu\nu\rho} \hat{D}_{38} + \left\{t g\right\}^{\mu\nu\rho} D_{312} + \left\{u g\right\}^{\mu\nu\rho} D_{313},
\]

where we have used the abbreviations \( t^\mu = (p_1 - k_1)^\mu \) and \( u^\mu = (p_1 - k_2)^\mu \). This compares favorably with (3.17). The other occurring boxes cannot be simplified like that, since the \( b \leftrightarrow d \) interchange has to be performed. There we can only check relations like \( D_{12} - \overline{D}_{12} = D_{13} - \overline{D}_{13} \), which always have to be fulfilled.

Finally, as has been mentioned already when introducing the projective momenta in (3.21) to (3.23), the Passarino-Veltman decomposition breaks down when the inverse of the matrix \( X \) does not exist. In our calculations this occurs only in simple bubble diagrams of the type depicted in Fig. 3.6, inserted in the incoming on-shell gluons. They
lead to integrals $B(k, m, m)$ with $k^2 = 0$ but $m \neq 0$. But here $X_B = k^2$, so obviously it cannot be inverted. The integral occurring in this situation is

$$I = \mu^{-2} \int \frac{d^n q}{(2\pi)^n} \frac{\text{Tr} \left\{ \gamma^\mu (\not{q} + m) \gamma^\nu (\not{k} + \not{\bar{m}}) \right\}}{(q^2 - m^2)((q + k)^2 - m^2)}$$

$$= 4\mu^{-2} \int_0^1 dx \int \frac{d^n q}{(2\pi)^n} \frac{2q^\mu q^\nu + (k^\mu q^\nu + q^\mu k^\nu) + (m^2 - k \cdot q - q^2)g^{\mu\nu}}{[q^2 + 2xk \cdot q - m^2 + k^2x]^2}$$

$$= -8(k^\mu k^\nu - g^{\mu\nu} k^2) \mu^{-2} \int_0^1 dx \ x(1 - x)I_0,$$

where we have used Equations (A.18)-(A.20) of [68], see also Appendix C of [69]. The basic integral $I_0$ is given to $O(1)$ by

$$I_0 = -\frac{i}{16\pi^2} \left[ \frac{2}{\varepsilon} + \gamma_E - \ln(4\pi) + \ln(k^2 x(1 - x) - m^2) \right],$$

with the Euler $\gamma_E$. If $m = 0 = k^2$, then $I_0 = 0$ and thus $I = 0$. Otherwise we get

$$I = \frac{i}{2\pi^2} (k^\mu k^\nu - g^{\mu\nu} k^2) \mu^{-2} \left\{ \frac{1}{6} \left[ \frac{2}{\varepsilon} + \gamma_E - \ln(4\pi) \right] \right. $$

$$+ \int_0^1 dx \ x(1 - x) \ln(k^2 x(1 - x) - m^2) \right\}. \quad (3.50)$$

This formula is valid in general, it is for example easy to obtain Equation (III.29) of [69] for $k^2, m \neq 0$ from it. But here we are interested in the case of $k^2 = 0$ with $m \neq 0$, and then using $C_e$ defined in (3.6) to $O(\varepsilon)$, we can write the integral to $O(1)$ as

$$I = iC_e (k^\mu k^\nu - k^2 g^{\mu\nu}) \frac{8}{3\varepsilon},$$

where we have kept $k^2$ in the Lorentz structure, since there will be a $1/k^2$ dependence due to a gluon propagator when attaching Fig. 3.6 to the rest of the Feynman diagram. The limit $k^2 \to 0$ is possible in the Lorentz structure only after contracting the Lorentz indices in the matrix element.
Chapter 4

Renormalization

4.1 The QCD Lagrangian and its Renormalization

The last chapter has shown that we encounter singularities when we calculate higher order corrections using the Feynman rules derived from the bare QCD Lagrangian. The infrared singularities cancel in the sum with the real contributions which will be introduced in the next chapter. This is guaranteed by the Bloch-Nordsieck and Kinoshita-Lee-Nauenberg theorems \cite{[70]}, respectively. The real contributions also have a new type of singularities called collinear or mass singularities, which will be dealt with by the mass factorization procedure of Chap. 6. Basically this amounts to a redefinition of the parton densities of the hadrons (and photons). This leaves us with the ultraviolet divergencies. We will see in this chapter how a redefinition of the fields and parameters of the bare Lagrangian can be used to eliminate the UV singularities. We note that details about our particular scheme for the renormalization of QCD, which uses the \( \overline{\text{MS}} \) scheme for light quarks and an on-shell scheme with explicit decoupling for the heavy quarks, cannot easily be found in the literature. In the corresponding unpolarized calculations, which also use this scheme, an effective procedure using only mass and strong coupling renormalization is used, see for example Eqns. (2.9)-(2.11) in \cite{[46]}. However, no derivations of the formulae are given, so we will supply them here. Furthermore, the only calculation of the needed renormalization constants \( Z_i \) known to us is \cite{[71]}, which however does not provide much technical detail on their derivation. Actually this reference was pointed out to us only after we had already (re-)calculated the \( Z_i \). Since the available information on this scheme seems to be scarce, we will provide sufficient detail of our independent calculation.

Let us start by writing down the bare QCD Lagrangian\(^1\). It can be split into parts

\[
\mathcal{L} = \mathcal{L}_G + \mathcal{L}_{GF} + \mathcal{L}_{FP} + \mathcal{L}_F = \mathcal{L}_0 + \mathcal{L}_1 ,
\]

(4.1)

where the parts are

\[
\mathcal{L}_G = \frac{1}{4} F_{\mu\nu}^a F^{a\mu\nu} \quad \text{with} \quad F_{\mu\nu}^a = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu ,
\]

(4.2)

\(^1\)The following derivation of the counterterm Feynman rules is standard and follows closely \cite{[64]}.

\[ \mathcal{L}_{GF} = -\frac{1}{2\alpha} (\partial^\mu A^a_\mu)^2 \quad \text{with} \quad \alpha = 1 \quad \text{in Feynman gauge}, \]  

(4.3)

Faddeev-Popov:  

\[ \mathcal{L}_{FP} = (\partial^\mu \xi^a) D^a_\mu \xi^b \quad \text{with} \quad D^a_\mu = \delta^a_\mu \partial^\mu - g f^{abc} A^c_\mu, \]  

(4.4)

fermion:  

\[ \mathcal{L}_F = \bar{\Psi}_i (i \slashed{D} - m \delta_{ij}) \Psi_j \quad \text{with} \quad D^a_\mu = \delta^a_\mu \partial^\mu - ig T^a_\mu A^\mu, \]  

(4.5)

where \( T^a \) and \( f^{abc} \) are the generators and structure constants of \( SU(3)_{\text{color}} \), respectively, and the “gluon” color indices can take the values \( a, b, c, \ldots = 1, \ldots, 8 \) and the “quark” ones can have \( i, j, \ldots = 1, 2, 3 \). See App. B.3 for more details about the \( SU(N) \) groups. Also the \( \xi^a \) and \( \xi^{a*} \) ghost fields should be viewed as independent, i.e., one could write \( \xi^a = (\xi^a_1 + i \xi^a_2)/\sqrt{2} \) with two independent real ghost fields \( \xi^a_1 \) and \( \xi^a_2 \). Furthermore, we have only written the fermion field for one quark flavor in (4.5) for simplicity. Splitting into a free part \( \mathcal{L}_0 \) and an interaction part \( \mathcal{L}_I \) then gives

\[ \mathcal{L}_0 = -\frac{1}{4} \left( \partial^\mu A^a_\mu - \partial_\mu A^a_\mu \right) \left( \partial^\nu A^{a\nu} - \partial^\nu A^{a\nu} \right) - \frac{1}{2\alpha} \left( \partial^\mu \xi^a \right)^2 \left( \partial^\mu \xi^a \right) + \bar{\Psi}_i (i \slashed{\partial} - m) \Psi_i, \]  

(4.6)

\[ \mathcal{L}_I = \frac{g}{2} f^{abc} \left( \partial^\mu A^a_\mu - \partial_\mu A^a_\mu \right) A^{b\mu} A^{c\nu} - \frac{g^2}{4} f^{abc} f^{ade} A^a_\mu A^b_\nu A^c_\rho A^d_\sigma - g f^{abc} \left( \partial^\mu \xi^a \right) \xi^b A^c_\mu + \bar{\Psi}_i T^a_\mu \gamma^\mu \Psi_j A^a_\mu. \]  

(4.7)

Now the bare Lagrangian (4.1) will be renormalized by introducing renormalization constants \( Z_i \)

\[ A^a_\mu = Z_3 A^a_\mu, \quad \xi^{a(\ast)} = Z_3 \xi^{a(\ast)}, \quad \Psi = Z_2 \Psi, \]  

(4.8)

\[ g = Z_2 g, \quad \alpha = Z_3 \alpha, \quad m = Z_m m. \]  

(4.9)

Note that the gauge fixing parameter \( \alpha \) is renormalized with the same constant as the gluon field. The reason can be seen by examining the Lorentz structure of the gluon propagator \( g^{\mu\nu} - (1 - \alpha)k^{\mu}k^{\nu}/k^2 \). A Slavnov-Taylor identity \( ik^\mu k^\nu \hat{D}^{ab}_\mu(k)/\alpha = \delta^{ab} \) for the full gluon propagator \( \hat{D}^{ab}_\mu \) can be derived, see [52, 53, 72] and App. B.4. It implies for the gluon self-energy \( \Pi^{ab}_\mu(k) \) that \( k^\mu k^\nu \Pi^{ab}_\mu(k) = 0 \), since \( \hat{D}^{ab}_\mu = D^{ab}_\mu + \Pi^{ab}_\mu \Pi^{ab}_\nu D^{ab}_\nu + \cdots \) with the free gluon propagator \( D^{ab}_\mu(k) = -i\delta^{ab}g_{\mu\nu} - (1 - \alpha)k^\mu k^\nu/k^2 \) and we see that only the transversal part of the gluon propagator will receive higher order corrections. Then only one multiplicative renormalization constant \( Z_3 \) is enough for the full gluon propagator, and from the Lorentz structure of the propagator one gets \( \alpha = Z_3 \alpha \).

Now we can insert (4.8) and (4.9) into (4.1) and obtain a renormalized Lagrangian

\[ \mathcal{L}_r = \mathcal{L}_0 + \mathcal{L}_I + \mathcal{L}_C. \]  

(4.10)

The first two terms are simply obtained from the free (4.6) and interaction (4.7) parts of the bare Lagrangian by adding a subscript “\( r \)” to every field and parameter, i.e., writing
down the bare Lagrangian structure with renormalized quantities. Obviously then $\mathcal{L}_C$ collects the $Z_i$ terms and we find

$$
\mathcal{L}_C = \frac{1}{2} (Z_3 - 1) \delta^{ab} \phi^a \left( g^{\mu \nu} - \partial^\mu \partial^\nu \right) \phi^b - (Z_3 h - 1) \delta^{ab} \phi^a \phi^b \\
+ (Z_2 - 1) \delta_{ij} \overline{\psi}_{i \alpha} (i \partial) \psi_{j \beta} + (Z_2 Z_m - 1) \delta_{ij} \overline{\psi}_{i \alpha} (-m_r) \psi_{j \beta} \\
- (Z_1 - 1) \frac{g r}{2} f^{abc} (\partial_\mu A^{a}_{\nu} - \partial_\nu A^{a}_{\mu}) A^{b}_{\mu} A^{c}_{\nu} - (Z_1 - 1) \frac{g r^2}{4} f^{abc} f^{ade} A^{b}_{\mu} A^{c}_{\nu} A^{d}_{\alpha} A^{e}_{\beta} \\
- (Z_{1h} - 1) g r f^{abc} (\partial^\mu \phi^a) \phi^b A^c_{\mu} + (Z_{1f} - 1) g r \overline{\psi}_{i \alpha} T^{\alpha \gamma}_{ij} \gamma^\mu \psi_{j \beta} A^{a}_{\gamma} \ , \quad (4.11)
$$

with

$$
Z_1 \equiv Z_g Z_3^2 \ , \quad Z_{1h} \equiv Z_g Z_{3h} \sqrt{Z_3} \ , \quad Z_{1f} \equiv Z_g Z_2 \sqrt{Z_3} \ , \quad Z_4 \equiv Z_g^2 Z_3^2 \ , \quad (4.12)
$$

and the first two terms of (4.11) are rewritten using the fact that a total divergence does not change the equations of motion.

For practical calculation one should now derive the Feynman rules from the Lagrangian. This derivation is lengthy but straightforward and can be found for example in [64], it will not be demonstrated here. But it is important to note the following point: $\mathcal{L}_0$ and $\mathcal{L}_f$ are identical to $\mathcal{L}_0$ and $\mathcal{L}_f$, respectively, in structure. The only difference is that every quantity has been replaced by the corresponding renormalized quantity. So we can simply use the bare QCD Feynman rules for them and set the coupling $g \to g_r$ and the mass $m \to m_r$ to the renormalized values! The new part of the renormalized Lagrangian $\mathcal{L}_C$ of course leads to additional Feynman rules. Note that we have written them in the form of new “interaction vertices”, which is possible since $\mathcal{L}_C$ is suppressed by powers of $g^2$. We will return to this point at the end of the next section. The last four terms of $\mathcal{L}_C$ are identical in structure to the terms in $\mathcal{L}_f$, so we can simply multiply the corresponding bare QCD vertex rules with the appropriate $(Z_i - 1)$ term. The first three terms are written in a form that allows us to (heuristically) read off the corresponding “vertex” rules by assuming the terms act on the $e^{-ik \cdot x}$ or $e^{-ip \cdot x}$ of a four-dimensional Fourier-transformation to momentum space, dropping the fields$^2$ and multiplying by a factor $i$. The set of new vertex rules we have found in this way are commonly called counterterms and we collect them in Tab. 4.1. Note that we have included a photon-quark counterterm, which is obtained in a completely similar manner as the gluon-quark counterterm from the QED Lagrangian$^3$. To avoid confusion with the QCD $Z_{1f}$, we have used the Ward identity $Z_{1f}^{\text{QED}} = Z_2 [73]$ for writing down the rule.

It is far from trivial to prove that the renormalizations introduced in (4.8) and (4.9) are sufficient in all orders to remove the UV singularities. For a thorough discussion one should turn to the appropriate literature, for example to [74]. On the other hand for a one-loop calculation such as ours this is easy to see. Basically for every type of diverging

---

$^2$The two gluon fields contribute a factor 2 for exchanging identical bosons.

$^3$But only QCD corrections are considered.
Table 4.1: The Feynman rules for the renormalization counterterms derived from $\mathcal{L}_C$ in (4.11). For convenience both directions of the ghost-gluon counterterm are shown. Also the photon-quark counterterm obtained similarly from the QED Lagrangian is included, where $e_q$ is the fractional quark charge and we do not consider QED corrections. $\alpha = e^2 / (4\pi) \simeq 1/137.$
loop we will also have one particular counterterm contribution, so that we can adjust the $Z_i$ to cancel the singularities. This will become clear in the next section, where the $Z_i$ will be worked out. One important point remains: We see from (4.12) that

$$Z_g \sqrt{Z_3} = \frac{Z_i}{Z_3} = \frac{Z_{h}}{Z_{h}} = \frac{Z_{1_f}}{Z_{2}} = \frac{Z_{1}}{Z_{j}}.$$  

(4.13)

This is the Slavnov-Taylor identity [52, 53, 72] for the renormalization constants. It appears to result trivially from our renormalization procedure, but this is only the case because we have assumed the universality of the renormalized coupling $g_r$ and hence that there is only one $Z_{g_r}$: $g = Z_{g}g_{r}$. In principle we could determine each of the $Z_i$ in Tab. 4.1 separately by calculating the corresponding loop diagram(s) and canceling their divergences. Then we could choose to regularize and subtract in such a way that (4.13) is violated. As one may intuitively guess from the involvement of the gauge coupling, this would amount to breaking the local gauge symmetry\(^4\) of the renormalized Lagrangian. A detailed discussion of these points is beyond the scope of this work and can be found for example in [74].

Important for our practical calculation is that we should choose a regularization procedure and a renormalization scheme which respects (4.13) and thus local gauge symmetry. Our choice of using dimensional regularization and the (modified) $\overline{\text{MS}}$ renormalization scheme fulfills this condition. By comparing Tab. 4.1 with (4.13), we realize that then we only need to calculate the 2PF $Z_i$ and one 3PF $Z_j$ of our choice. Each 3PF $Z_j$ is related to a corresponding 2PF $Z_i$ in exactly the same way as the gluon 4PF $Z_4$ is to the gluon 3PF $Z_1$. In the following section the renormalization constants $Z_{3i}$, $Z_{4i}$, $Z_3$, $Z_2$, and $Z_m$ will be calculated at one-loop. The remaining $Z_1$, $Z_4$ and $Z_{1_f}$ are then obtained by using (4.13). In this way local gauge symmetry allows us to obtain results that would require quite complicated calculations for free!

4.2 Renormalization Constants and Scheme Choice

Our scheme choice will be the following [43, 42, 46]: we wish to have $n_{lf}$ light flavors active in the running of $\alpha_s$ and in the parton evolution in addition to one produced heavy flavor, i.e., the total number of flavors is $n_f = n_{lf} + 1$. To this end we renormalize the light flavors using the standard $\overline{\text{MS}}$ prescription. The heavy (anti)quark is however renormalized on-shell and furthermore we remove the heavy quark loop contribution to the gluon self-energy, see the calculation of $Z_2$ below, which explicitly decouples the heavy (anti)quark at low energies. This modified $\overline{\text{MS}}$ fixed flavor scheme, which singles out the heavy (anti)quark according to its pole mass scale $m$, will be called $\overline{\text{MS}}_m$ henceforth. We will use the Feynman gauge\(^5\) and $n = 4 + \varepsilon$ in all our calculations. This is a variant of

\(^4\)More precisely, due to the terms $L_{GR}$ and $L_{FP}$, the Lagrangian is Becchi-Rouet-Stora (BRS) symmetric [75], see also App. B.4. So it is BRS symmetry that would be violated.

\(^5\)This implies that the renormalized gauge parameter $\alpha_r = 1$.  

43
the Collins, Wilczek and Zee scheme [76, 71], whose factorization properties have been worked out explicitly in [77].

\[ \tilde{\Pi}(k^2) = \int \frac{d^ng\cdot q}{(2\pi)^n} \frac{k^2 + k \cdot q}{q^2(k + q)^2} \]

\[ = C_A \delta^{ab} g_a^2 k^2 \left( \frac{2}{\varepsilon} \Gamma \left( 1 - \frac{2}{3} \right) \left( \frac{k^2}{\mu^2} \right) \right) \int_0^1 dx \pi x(1 - x)^{1 + \frac{2}{3}} \]

\[ = - C_A \delta^{ab} \frac{g_a^2}{32\pi^2} k^2 \left[ \frac{2}{\varepsilon} - 2 + \ln \left( \frac{k^2}{\mu^2} \right) \right]. \quad (4.14) \]

Here and in the following we have made frequent use of standard Feynman integral relations for “simple” cases. One can find them for example in Appendix A of [68] and Appendix C of [69]. We have defined the typical pole related terms

\[ \frac{2}{\varepsilon} = \frac{2}{\varepsilon} + \gamma_E - \ln(4\pi) \quad \text{and} \quad \frac{2}{\varepsilon} = \frac{2}{\varepsilon} - \ln \frac{\mu^2}{m^2}, \quad (4.15) \]

where \( \frac{2}{\varepsilon} \) will occur later on. It is just this \( \frac{2}{\varepsilon} \) combination of pole and finite terms which is subtracted in \( \overline{\text{MS}} \). The counterterm comes with a factor \( i \), see Tab. 4.1, and so we set

\[ Z_{\text{gh}} - 1 = - C_A \frac{g_a^2}{32\pi^2} \frac{2}{\varepsilon}. \quad (4.16) \]

The convention of having a factor \( -i \) comes from considering this correction as a term in a geometric sum, see the discussion at (4.52) below.
Next we add both ghost vertex contributions

\[
\hat{\Gamma}^\mu(k) = i \frac{C_A}{2} \int \frac{d^nq}{(2\pi)^n} \frac{(b) - (c)}{q^2(k + q)^2(k + q)^2}
\]

with

\[
(b) = \left[ k \cdot (k + q)(k + q)^\mu \right],
\]

\[
(c) = \left[ g^\mu (k^2 - 2k \cdot \bar{k} + \bar{k} \cdot k + q) + \bar{k}^\mu (-q^2 - k \cdot q + \bar{k} \cdot q) + \bar{k}^\mu k \cdot q \right]
\]

\[
\hat{\Gamma}^\mu(k) = i \frac{C_A}{2} \int \frac{d^nq}{(2\pi)^n} \frac{k}{q^2(k + q)^2} \left[ 2 \left( \frac{2}{\varepsilon} \right) - 2 \ln \left( \frac{k^2}{\mu^2} \right) \right],
\]

where we have used the non-trivial fact that \( \bar{k}^\mu \) can be set zero without influencing the singularity structure [69], to shorten our presentation. We can immediately read off the \( \overline{\text{MS}} \) renormalization constant

\[
Z_{1h} - 1 = C_A \frac{g_r^2}{32\pi^2} \frac{2}{\varepsilon}.
\]

Thus we can determine to \( O(g_r^2) \)

\[
Z_g \sqrt{Z_3} = Z_{1h} + Z_{3b} = 1 + C_A \frac{g_r^2}{16\pi^2} \frac{2}{\varepsilon},
\]

which confirms the naïve expectation that pure gauge loops get a “non-abelian” \( C_A \) contribution only.

![Figure 4.2: The loop contributions needed for the calculation of \( Z_3 \): (a)+(b) gauge loops, (c) vanishing gluon tadpole, and (d) massless and massive quark loop.](image)

The obvious next step is to calculate \( Z_3 \). The needed loop diagrams are shown in Fig. 4.2 and we equate \(-i\Pi^{\mu\nu}\) to them. It is not difficult to calculate these contributions directly, however for brevity we here use the fact, mentioned already in the last section, that we know their Lorentz structure due to the Slavnov Taylor identity (B.31):

\[
\Pi^{ab}_{\mu\nu}(k) = \delta^{ab} \left( k_{\mu} k_{\nu} - k^2 g_{\mu\nu} \right) \Pi(k^2) \quad \delta^{ab} \Pi(k^2) = -\frac{1}{(3 + \varepsilon)k^2} g^{\mu\nu} \Pi^{ab}_{\mu\nu}.
\]
Thus we will only calculate the $\Pi(k^2)$. Next we see immediately that the tadpole contribution Fig. 4.2 (c) vanishes, since it leads to an integral of the type (3.3). We must treat the gluon and ghost loops together, since only their sum will conform to (4.20). Their color factor is of course the same as for the ghost self-energy. Note that we have to multiply the loops with two identical particles by $1/2!$ and $-1$ due to the boson and fermion statistics, respectively. After the Lorentz contraction and dropping terms of the type (3.3), we obtain the simple integral

$$
\Pi(k^2) \overset{(a)+(b)}{=} iC_A \frac{g^2 \mu^{-\varepsilon}}{(3 + \varepsilon) k^2} \int \frac{d^n q}{(2\pi)^n} \frac{(8 + 3\varepsilon) k \cdot q - k^2}{q^2(q + k)^2} \\
= C_A \frac{g^2}{3 + \varepsilon} \left( -\frac{2}{\varepsilon} \right) \Gamma \left( 1 - \frac{\varepsilon}{2} \right) \left( \frac{k^2}{\mu^2} \right)^{\frac{\varepsilon}{2}} \int_0^1 dx [(8 + 3\varepsilon)x + 1]x^{\frac{\varepsilon}{2}}(1 - x)^{\frac{\varepsilon}{2}} \\
= -C_A \frac{g^2}{16\pi^2} \frac{5}{3} \left[ \frac{2}{\varepsilon} \ln \left( \frac{k^2}{\mu^2} \right) - \frac{31}{15} \right].
$$

(4.21)

The quark loop contribution Fig. 4.2 (d) has to be calculated both for massive and massless quarks. For one quark flavor we have

$$
\Pi(k^2) \overset{(d)}{=} iC_A \frac{g^2 \mu^{-\varepsilon}}{2(3 + \varepsilon) k^2} \int \frac{d^n q}{(2\pi)^n} \text{Tr} \left[ \gamma^\mu(q + m_r)\gamma_\mu(q + \bar{k} + m_r) \right] \\
= \frac{g^2}{4\pi^2} \mu^{-\varepsilon} \left\{ \frac{1}{6} \frac{2}{\varepsilon} + \int_0^1 dx x(1 - x) \ln \left[ -k^2x(1 - x) + m_r^2 \right] \right\} \\
= \frac{g^2}{4\pi^2} \frac{1}{6} \left\{ \frac{2}{\varepsilon} + \ln \left( \frac{k^2}{\mu^2} \right) - \frac{5}{3} \right\} \text{for } m_r = 0 \\
= \frac{g^2}{4\pi^2} \frac{1}{6} \left\{ \frac{2}{\varepsilon} - \frac{5}{3} - \frac{4m_r^2}{k^2} - \left( 1 + \frac{m_r^2}{k^2} \right) b_k \ln \left( -x_k \right) \right\} \text{for } m_r \neq 0,
$$

(4.22)

with $b_k = \sqrt{1 - 4m_r^2/k^2}$ and $x_k = (1 - b_k)/(1 + b_k)$. Here we see the basic problem of a pure $\overline{\text{MS}}$ treatment when quark masses come into play. The gauge (4.21) and massless quark parts have a $\ln(-k^2/\mu^2)$ term, whereas the heavy quark part has a $\ln(\mu^2/m_r^2)$ term from the $\varepsilon_m$. But for low energies $k^2 \ll m_r^2$, this means that no matter what the arbitrary mass scale $\mu$ is, we will keep at least one large logarithm after subtracting only the poles. So here we deviate from the pure $\overline{\text{MS}}$ treatment and do not ignore the (finite) logarithm depending on the heavy quark mass.

Then the total sum of (4.21), of $n_f$ light flavors, and of one heavy flavor is

$$
\Pi(k^2) = \frac{g^2}{16\pi^2} \left[ -\frac{5}{3} C_A \frac{2}{\varepsilon} + n_f \frac{2}{3} \frac{2}{\varepsilon} + \frac{2}{3} \varepsilon_m + \ldots \right] \\
= \frac{g^2}{16\pi^2} \left[ (2C_A - \beta_0) \frac{2}{\varepsilon} + \frac{2}{3} \varepsilon_m + \ldots \right] \\
= \frac{g^2}{16\pi^2} \left[ (2C_A - \beta_0) \frac{2}{\varepsilon} - \frac{2}{3} \ln \left( \frac{\mu^2}{m_r^2} \right) + \ldots \right],
$$

(4.23)
with \( \beta_0 = (11C_A - 2n_f)/3 \) and \( \beta'_0 = (11C_A - 2n_f)/3 \) and the dots stand for the remaining finite terms. It becomes obvious from the last line in (4.23) that our choice

\[
Z_3 - 1 = \frac{g^2_{\text{F}}}{16\pi^2} \left[ (2C_A - \beta_0) \frac{2}{\bar{\varepsilon}} + \frac{2}{3} \frac{2}{\bar{\varepsilon}_m} \right] = \frac{g^2_{\text{F}}}{16\pi^2} \left[ (2C_A - \beta'_0) \frac{2}{\bar{\varepsilon}} - \frac{2}{3} \ln \left( \frac{\mu^2}{m_r^2} \right) \right] \tag{4.24}
\]

does not only subtract the usual \( \overline{\text{MS}} \) term \( (2C_A - \beta_0) \frac{2}{\bar{\varepsilon}} \), but in addition the \( \ln(\mu^2/m_r^2) \) term. Note that if we had calculated (4.22) with \( m_r^2 = k^2 = 0 \), it would have given zero\(^7\). But with \( k^2 = 0 \) and \( m_r^2 \neq 0 \) the integral gives \(-\frac{g^2_{\text{F}}}{\pi^2} \frac{1}{6} \bar{\varepsilon}_m \). This term is exactly eliminated by our subtraction, whereas the normal \( \overline{\text{MS}} \) prescription would leave the \( \ln(\mu^2/m_r^2) \) term. Thus we see that in the limit of small energies \( k^\mu \to 0 \) flowing into the heavy quark loop (and actually for all light-like momenta, as encountered in external partonic legs), the heavy quarks explicitly decouple with the prescription used here.

From (4.24) and (4.19) we directly obtain

\[
Z_3 - 1 = \frac{g^2_{\text{F}}}{32\pi^2} \left[ \beta_0 \frac{2}{\bar{\varepsilon}} - \frac{2}{3} \frac{2}{\bar{\varepsilon}_m} \right]. \tag{4.25}
\]

At this point a short digression concerning the renormalization group equation (RGE) is helpful, in order to derive the effect of our choice on the running coupling. First note that the action \( \int d^n x L \) should be dimensionless, which means that the dimension of the Lagrangian density \([L]=\text{mass}^n\). By inspecting (4.1), we can directly determine the dimensions of the parameters and fields. In particular we find \([g]=\text{mass}^{(4-n)/2}\) and similarly from (4.10) \([g_r]=\text{mass}^{(4-n)/2}\). So let us define a mass scale for the bare and renormalized coupling

\[
g \equiv \tilde{g}(\mu_b) \mu_b^{-\frac{\tau}{2}} \quad \text{and} \quad g_r \equiv \tilde{g}_r(\mu) \mu^{-\frac{\tau}{2}}. \tag{4.26}
\]

Here \( \tilde{g} \) and \( \tilde{g}_r \) are dimensionless quantities. Also \( g \) and \( g_r \) do not depend on the scales \( \mu_b \) and \( \mu \). However, if we take a look at our treatment of the loop integrals until now, e.g., the self-energy (4.22), we see that we have treated \( g_r \) as being dimensionless and introduced an arbitrary mass scale \( \mu \) to keep the correct dimensionality of the occurring integrals. It is obvious from (4.26) that we should have more precisely written

\[
g_r \to \tilde{g}_r(\mu) \quad \sim \quad Z_g(g_r, \mu) \to Z_g[\tilde{g}_r(\mu), \mu], \tag{4.27}
\]

in the results obtained so far. Note that \( \tilde{g}_r \) depends explicitly on the scale \( \mu \). Performing the replacements in \( g = Z_g g_r \) and inserting (4.26) gives

\[
\tilde{g}_r(\mu) = \left( \frac{\mu_b}{\mu} \right)^{-\frac{\tau}{2}} \frac{\tilde{g}(\mu_b)}{Z_g[\tilde{g}_r(\mu), \mu]}. \tag{4.28}
\]

\(^7\) The expansion to the logarithmic integral is not valid then, the integral is of the same type as (3.3).
By simple differentiation we obtain

$$
\beta \equiv \mu \frac{d\tilde{g}_r(\mu)}{d\mu} = \left( \frac{\varepsilon}{2} - \frac{\mu}{Z_g} \frac{dZ_g(\tilde{g}_r, \mu)}{d\mu} \right) \tilde{g}_r(\mu)
$$

$$
= \left( \frac{\varepsilon}{2} - \frac{\mu}{Z_g} \frac{\partial Z_g(\tilde{g}_r, \mu)}{\partial \mu} - \frac{\mu}{Z_g} \frac{d\mu}{d\mu} \frac{\partial Z_g(\tilde{g}_r, \mu)}{\partial \mu} \right) \tilde{g}_r(\mu)
$$

$$
= \frac{\beta_0 \tilde{g}_r^2(\mu)}{16\pi^2} + \mathcal{O}(\tilde{g}_r^3, \varepsilon). \quad (4.29)
$$

In the last step we have used the fact that the $d\mu/d\mu$ term only contributes at $\mathcal{O}(\tilde{g}_r^3)$. Note that this result means that in the running coupling only the $n_f$ light flavors contribute due to our choices for $Z_g$. The contribution of the heavy quark flavor cancels due to the subtraction of the massive loop logarithm, i.e., because of the explicit decoupling of the heavy quark at small energies. Without this subtraction, we would have found $\beta_0^H$ with $n_f = n_{fj} + 1$ flavors instead.

With $\alpha_s = \tilde{g}_r^2/(4\pi)$ we can immediately obtain from (4.29) the RGE of the running coupling constant at LO

$$
\frac{d\alpha_s(\mu^2)}{d\ln(\mu^2)} = -\frac{\beta_0}{4\pi} \alpha_s^2(\mu^2) + \mathcal{O}(\alpha_s^3) \quad (4.30)
$$

The solution is easily obtained as

$$
\alpha_s(\mu_t^2) = \frac{\alpha_s(\mu_0^2)}{1 + \alpha_s(\mu_0^2) \frac{4\pi}{\beta_0} \ln \frac{\mu_t^2}{\mu_0^2}} = \frac{4\pi}{\beta_0 \ln \frac{\mu_t^2}{\mu_0^2}}, \quad (4.31)
$$

$$
\Lambda_{\text{LO}}^2 = \mu_0^2 \exp \left[ -\frac{4\pi}{\beta_0 \alpha_s(\mu_0^2)} \right]. \quad (4.32)
$$

In (4.31) we have integrated from a scale at which we renormalize the coupling, $\mu_0^2$, to a large scale, $\mu_t^2$, at which we chose to evaluate $\alpha_s$, i.e., we use $\alpha_s(\mu^2 = \mu_t^2)$ in our final results. We see here the property of asymptotic freedom, i.e., for $\mu_t^2 \to \infty$ (and fixed small $\mu_0^2$) the coupling constant $\alpha_s \to 0$, which of course is the reason why the expansion in $\alpha_s$ we have been using is justified for a large scale $\mu_t^2$. Due to $\mu = \mu_t$, we find in our cross sections logarithms $\ln(\mu_t/m)$ depending on a typical scale $m$ of the process. To prevent these terms from becoming large, we must set $\mu_t$ approximately equal to this typical scale. So we need a large scale $m$, provided in our cases by the heavy quark mass. In (4.32) we have introduced the QCD scale parameter in LO $\Lambda_{\text{LO}}$, which brings our result for the running coupling in a convenient form. It is, apart from the quark masses, the only free parameter of QCD and has to be determined by experiment. Note that we require $\alpha_s$ to be continuous when changing the number of (light) flavors, which is still possible at NLO. We will follow the usual prescription of doing so at the quark mass scales. This means $\Lambda_{\text{LO}}^2$ has to be adjusted at these thresholds accordingly and we
4.2. Renormalization Constants and Scheme Choice

will have to quote the number of (light) flavors when stating the value used for it. We see that the dimensionless coupling constant at the renormalization point \( \alpha_s(\mu_0^2) \) and the renormalization point scale \( \mu_0 \) itself are hidden in (4.31) by the introduction of the mass scale \( \Lambda_{\text{LO}}^2 \) in (4.32). This is an example of “dimensional transmutation” [78]. Thus only \( \mu_0 \) will appear in our results and so it, and not \( \mu_0 \), is usually called the renormalization scale. As a final point we note that taking two loop corrections into account, we would find for (4.29) and (4.30)

\[
\beta \equiv \mu \frac{d \tilde{g}_\mu}{d \mu} = -\beta_0 \frac{\tilde{g}_\mu^2}{16\pi^2} - \beta_1 \frac{\tilde{g}_\mu^2}{(16\pi^2)^2} + \mathcal{O}(\tilde{g}_\mu^2, \varepsilon). \tag{4.33}
\]

\[
\frac{d \alpha_s(\mu^2)}{d \ln(\mu^2)} = -\frac{\beta_0}{4\pi} \alpha_s^2(\mu^2) - \frac{\beta_1}{(4\pi)^2} \alpha_s^3(\mu^2) + \mathcal{O}(\alpha_s^4) \tag{4.34}
\]

Where we have the new coefficient \( \beta_1 = 102 - \frac{38}{3} n_f \) [79]. Thus the two-loop correction to the running coupling is of relative order \( \tilde{g}_\mu^2 \sim \alpha_s \). If we now use the running coupling in the LO part of our calculation, this two-loop correction to the coupling leads to a contribution of the same order as the NLO part! Thus it should be used when we calculate in NLO. In practice we will follow the usual prescription of using (4.31) when calculating in LO, and the solution of (4.33) when calculating in NLO\(^9\). To obtain a solution of (4.34), we must integrate

\[
\ln \frac{\mu_0^2}{\mu_0^2} = \int_{\alpha_s(\mu_0^2)}^{\alpha_s(\mu^2)} \frac{d \alpha_s}{\alpha_s^2 - \frac{\beta_0}{4\pi} \alpha_s - \frac{\beta_1}{(4\pi)^2} \alpha_s^3} \tag{4.35}
\]

and obtain after again absorbing \( \alpha_s(\mu_0^2) \) for convenience

\[
L \equiv \ln \frac{\mu_0^2}{\Lambda_{\text{NLO}}^2} = \frac{4\pi}{\beta_0 \alpha_s(\mu_0^2)} - \frac{\beta_1}{\beta_0^2} \ln \left[ \frac{4\pi}{\beta_0 \alpha_s(\mu_0^2)} + \frac{\beta_1}{\beta_0^2} \right], \tag{4.36}
\]

\[
\Lambda_{\text{NLO}}^2 \equiv \mu_0^2 \exp \left[ -\frac{4\pi}{\beta_0 \alpha_s(\mu_0^2)} \right] \left( \frac{4\pi}{\beta_0 \alpha_s(\mu_0^2)} + \frac{\beta_1}{\beta_0^2} \right)^{\frac{\beta_1}{\beta_0^2}}. \tag{4.37}
\]

We can now solve (4.36) numerically, given a value for \( \Lambda_{\text{NLO}} \), for \( \alpha_s(\mu_0^2) \) at any \( \mu_0^2 \). Alternatively an approximate solution of (4.36) can be obtained by iteration and expansion in \( 1/L \). The first iteration at \( \mathcal{O}(1/L^2) \) then yields

\[
\alpha_s(\mu^2) = \frac{4\pi}{\beta_0 \ln \frac{\mu^2}{\Lambda_{\text{NLO}}^2}} \left[ 1 - \frac{\beta_1}{\beta_0^2} \ln \left( \ln \frac{\mu^2}{\Lambda_{\text{NLO}}^2} \right) \right]. \tag{4.38}
\]

---

\(^8\)Subtracting the heavy quark loop contributions at \( k^2 = 0 \) in \( \overline{\text{MS}} \) naturally leads to the well-known \( \overline{\text{MS}} \) results, but with \( n_f \to n_f = n_f - 1 \).

\(^9\)The error of using the two loop correction to \( \alpha_s \) with the NLO part is next-to-NLO (NNLO).
and this formula will be used in our calculations for the NLO running coupling, since a typical scale $\mu_r$ in our processes is of the order of the heavy quark mass and then the deviation between a numerical solution of (4.36) and (4.38) is below 1% even for the charm mass with $m_f = 3$. In the remainder of the chapter we will again use our old notation with $g_\ast$ instead of $\tilde{g}_\ast(\mu)$ for brevity, but the identification (4.27) and the scale of evaluation $\mu = \mu_r$ are implied.

Back to the calculation of the renormalization constants: $Z_3$ together with (4.13) also allows us to easily derive

\[
Z_1 - 1 = -\frac{g_\ast^2}{16\pi^2} \frac{2}{3} \left[ C_A \frac{2}{\varepsilon} - \left( n_f \frac{2}{\varepsilon} + \frac{2}{\varepsilon_m} \right) \right], \tag{4.39}
\]

\[
Z_1 - 1 = -\frac{g_\ast^2}{16\pi^2} \frac{1}{3} \left[ C_A \frac{2}{\varepsilon} + 2 \left( n_f \frac{2}{\varepsilon} + \frac{2}{\varepsilon_m} \right) \right], \tag{4.40}
\]

which completes the gauge sector counterterms. The only missing piece is the quark sector and it is sufficient to calculate the quark self-energy displayed in Fig. 4.3 to determine it. Before we start, let us motivate our scheme choices. For the light quarks we will use the usual \textit{MS} scheme throughout. But the heavy quark will be treated differently. We use the \textit{on-shell} prescription to fix the renormalized mass at the pole mass. The pole mass is the only mass parameter of perturbative QCD which is independent of the renormalization scale, renormalization scheme, and gauge parameter and is IR insensitive [80], thus it is certainly a “good” mass scale to use. Furthermore, we note that the Slavnov-Taylor identity we need for being allowed to eliminate the unphysical gluon polarizations with external ghosts\textsuperscript{10}, is only valid if additional external lines are \textit{on-shell}! Since the renormalization procedure keeps massless particles massless, gluons and light quarks are on-shell anyway. But we need to renormalize the heavy quark mass on-shell as well, if we wish to use the “ghost trick” in our calculations.

\[
\begin{array}{c}
\text{Figure 4.3: The quark self-energy loop contribution needed for the calculation of } Z_m \text{ and } Z_2.
\end{array}
\]

The general expression for the quark self-energy can be read off the loop diagram Fig. 4.3. We set $-i\Sigma$ equal to the (truncated) loop and obtain

\[
\Sigma(\phi, m_c) = -i\delta_{ij}C_F g_\ast^2 \mu^{-\varepsilon} \int \frac{d^nq}{(2\pi)^n} \frac{1}{q^2 - \gamma^\mu \gamma_\mu} \frac{1}{\phi + \bar{q} - m_r} \gamma_\mu
\]

\textsuperscript{10}External ghosts appear in our unpolarized calculation since we use the metric instead of the physical polarization tensor, see (2.15).
\[ \begin{align*}
&= -i\delta_{ij} C_F g_r^2 \mu^{-\varepsilon} \int_0^1 dx \int d^n q \frac{(2 - n)(1 - x)\psi + nm_r}{(2\pi)^n [q^2 - (x m_r^2 - x(1 - x)p^2)]^2} \\
&= \delta_{ij} C_F g_r^2 \mu^{-\varepsilon} \frac{\Gamma(1 - \frac{\varepsilon}{2})}{(16\pi^2)^{1 + \frac{\varepsilon}{2}}} \left( -\frac{2}{\varepsilon} \right) \mathcal{J} \tag{4.41}
\end{align*} \]

We have already performed the sum over loop colors: \( T^a_{ji} T^a_{ii} = C_F \delta_{ij} \). Note that the divergence already is manifest, thus the integral \( \mathcal{J} \) must be finite and can be expanded in \( \varepsilon \), due to the pole \( 1/\varepsilon \) in (4.41), we must calculate it to \( \mathcal{O}(\varepsilon) \):

\[ \mathcal{J} = \int_0^1 dx \left[ -(2 + \varepsilon)(1 - x)\psi + m_r(4 + \varepsilon)[x m_r^2 - x(1 - x)p^2]\right] \]

\[ = m_r \left\{ 3 + \frac{\varepsilon}{2} \left[ -5 + m_r^2 \frac{m_r^2}{p^2} - m_r^2 \left( \frac{m_r^2}{p^2} - 4 \right) \ln m_r^2 + \left( 3 - 4m_r^2 \frac{m_r^4}{p^4} + m_r^4 \right) \ln(m_r^2 - p^2) \right] \right\} \]

\[ + (\psi - m_r) \left\{ -1 + \frac{\varepsilon}{2} \left[ 1 + m_r^2 \frac{m_r^2}{p^2} - m_r^2 \frac{m_r^4}{p^4} \ln m_r^2 + \left( \frac{m_r^4}{p^4} - 1 \right) \ln(m_r^2 - p^2) \right] \right\} + \mathcal{O}(\varepsilon^2) \tag{4.42} \]

Inserting this back into (4.41) and expanding in \( \varepsilon \), we get the final result

\[ \begin{align*}
\Sigma(\psi, m_r) &= \delta_{ij} [A m_r + B(\psi - m_r)] \tag{4.43} \\
A &= -C_F \frac{g_r^2}{16\pi^2} \left[ 3 \left( \frac{2}{\varepsilon} - \ln \frac{m_r^2}{m_r^2} \right) - 5 + m_r^2 \frac{m_r^2}{p^2} + \left( 3 - 4m_r^2 \frac{m_r^4}{p^4} + m_r^4 \right) \ln \frac{m_r^2}{m_r^2} - p^2 \right], \\
B &= -C_F \frac{g_r^2}{16\pi^2} \left[ - \left( \frac{2}{\varepsilon} - \ln \frac{m_r^2}{m_r^2} \right) + 1 + m_r^2 \frac{m_r^2}{p^2} + \left( \frac{m_r^4}{p^4} - 1 \right) \ln \frac{m_r^2}{m_r^2} - p^2 \right].
\end{align*} \]

We see from Tab. 4.1 that the counterterm contribution, obtained similarly to (4.41) by equating \(-i\Sigma_C\) to the counterterm insertion, is

\[ \Sigma_C = -\delta_{ij} [(Z_2 - 1)\psi - (Z_2 Z_m - 1)m_r] \overset{O(\alpha^2)}{\sim} \delta_{ij} [(Z_m - 1)m_r - (Z_2 - 1)(\psi - m_r)] \]

\[ \tag{4.44} \]

where we have used the general structure \( Z_i = 1 + \alpha_i z_i + \mathcal{O}(\alpha_i^2) \) of the renormalization constants to separate the contributions. Thus the sum of (4.43) and (4.44) is

\[ \Sigma + \Sigma_C = \delta_{ij} \left\{ [A + (Z_m - 1)]m_r + [B - (Z_2 - 1)](\psi - m_r) \right\} \]

\[ \tag{4.45} \]

and has to be (UV) finite.

The \( \overline{\text{MS}} \) prescription used for \( m_r = 0 \) requires the subtraction of only the \( 2/\varepsilon \) pole, see (4.15). So from (4.45) we directly see

\[ m_r = 0 : \quad Z_m - 1 = \frac{g_r^2}{16\pi^2} C_F \frac{6}{\varepsilon} \quad \text{and} \quad Z_2 - 1 = \frac{g_r^2}{16\pi^2} C_F \frac{2}{\varepsilon}. \]

\[ \tag{4.46} \]
In practical calculations we do not need \( Z_m \) for the massless quarks, since then the \( Z_m \) counterterm part vanishes, see (4.44). For the heavy quarks we will renormalize the mass on-shell as discussed above. This means the inverse propagator (the proper two-point function), which is given by

\[
\Gamma^{(2)}(\phi, m_r) = -i[\phi - m_r - (\Sigma + \Sigma_C)],
\]

is supposed to become zero at \( \hat{p} = m_r \), so the condition we use is

\[
m_r \neq 0 : \quad (\Sigma + \Sigma_C)|_{\hat{p} = m_r} = 0 \quad \Rightarrow \quad Z_m - 1 = -A|_{\hat{p} = m_r}.
\]

(4.47)

We now have to choose a way to also determine \( Z_2 \). Since we are going to determine \( Z_{1f} \) from (4.13), any choice will respect the Slavnov-Taylor identities by construction. We chose here the simplest possible extension\(^{11}\) of the \( \overline{\text{MS}} \) choice, which subtracts the mass logarithm \( \ln(\mu^2/m^2) \) as well

\[
m_r \neq 0 : \quad Z_m - 1 = C_F \frac{g_r^2}{16\pi^2} \left( \frac{6}{\hat{\varepsilon}_m} - 4 \right) \quad \text{and} \quad Z_2 - 1 = C_A \frac{g_r^2}{16\pi^2} \frac{2}{\hat{\varepsilon}_m}.
\]

(4.48)

Now we can immediately derive the last missing renormalization constant, the quark-gluon vertex correction, from (4.13) to be

\[
Z_{1f} = Z_2 + C_A \frac{g_r^2}{16\pi^2} \frac{2}{\hat{\varepsilon}_m},
\]

(4.49)

where for massless quarks at the vertex one inserts \( Z_2 \) from (4.46) and for massive ones from (4.48).

After completing the derivation of the renormalization constants, we should come back to their application. First let us reconsider why we were allowed to write down “interaction vertices” even for those three first terms of \( \mathcal{L}_C \) (4.11) which should have by analogy yielded propagator rules. To this end consider the simpler example of the well-known Klein-Gordon Lagrangian for a free massive field

\[
\mathcal{L} = \frac{1}{2}(\partial_\mu \phi)(\partial^\mu \phi) - \frac{1}{2}m^2 \phi^2
\]

(4.50)

and interpret it as the Lagrangian of a massless field with an interaction given by the second term. Then we have the Feynman rules

\[
\begin{align*}
\begin{array}{c}
\text{\textbullet} & \quad \frac{i}{p^2}, \\
\text{\textbullet} \quad \text{\textbullet} & \quad -im^2,
\end{array}
\end{align*}
\]

(4.51)

and the massive propagator appears as an infinite sum of interactions

\[
\begin{align*}
\begin{array}{c}
\text{\textbullet} \quad \text{\textbullet} & \quad = \quad \frac{i}{p^2} + \frac{i}{p^2}(-im^2) \frac{i}{p^2} + \frac{i}{p^2}(-im^2) \frac{i}{p^2}(-im^2) \frac{i}{p^2} + \ldots \\
& \quad = \frac{i}{p^2 - m^2}.
\end{array}
\end{align*}
\]

(4.52)

\(^{11}\)With this choice the derivative of the inverse propagator \( \partial \Gamma^{(2)}(\phi, m_r)/\partial \hat{p} \) remains finite for \( \hat{p} \to 0 \), compare also [76, 71].
Similarly, in our case we could have derived “counter-propagator” rules, and they would have corresponded to an infinite sum of counter-interactions. However, each of the counter-interactions is suppressed by $\alpha_s$. Hence for our one loop calculation it is sufficient to stop the series after only the first two-point interaction counterterm, all other terms would be of higher order. For this reason we have interpreted the first three rules in Tab. 4.1 as “vertices”. Note that the first interaction of a counterterm will always contribute negatively, since it is defined as $i$ instead of the $-im^2$ above. For example take the ghost counterterm put on a propagator line. Then instead of just one propagator, we have the propagator, then the counterterm and then again the same propagator:

$$
\left[ i\delta_{ac} \frac{1}{k^2} \right] i(Z_{3h} - 1) \delta^{ad} k^2 \left[ i\delta_{ab} \frac{1}{k^2} \right] = -(Z_{3h} - 1) \left[ i\delta_{ab} \frac{1}{k^2} \right],
$$

(4.53)

compared to the one propagator $i\delta_{ab}/k^2$ we had before, just a factor $-(Z_{3h} - 1)$ appears. It is also clear, that counterterm contributions only come from inserting elements from Tab. 4.1 into graphs of at least one order in $\alpha_s$ below the highest order being calculated, since the elements are of order $\alpha_s$ themselves. This means for our NLO calculation, that we will just insert them in the LO graphs. Let us assume that mass renormalization with $Z_m$ has already been performed on-shell, as discussed above, then (4.44) will give similarly a factor $-(Z_2 - 1)$ when inserted at a quark propagator. For the gluon two point counterterm inserted at a quark propagator, we get a factor $-(Z_3 - 1)$ for the same reason\(^\text{12}\). On the other hand the lower four counterterms in Tab. 4.1 have exactly the same structure as the bare Feynman rules. So for example replacing the quark-gluon vertex by the quark-gluon three-point counterterm will just yield a factor $(Z_{1/2} - 1)$ and so on.

Thus we conclude, that upon inserting the renormalization counterterms in the LO graphs, we will simply get the LO amplitudes times a sum of appropriate factors $-(Z_i - 1)$ for each propagator and appropriate factors $Z_i - 1$ for each vertex. What about external lines? We can insert two-point counterterms there as well, getting contributions with a factor $-(Z_i - 1)$. But we must remember that according to (4.8), for example an outgoing electron will now appear in the amplitudes as $u = \sqrt{Z_2} u_r$. Since we have always the same external legs in coherently added amplitudes, we can factor out these terms, and use only the renormalized fields, like $u_r$, in the amplitudes. However, since $Z_i = 1 + \alpha_s z_i$, the factor obtained from $k$ external (anti)quarks, $l$ external gluons and $m$ external ghosts (keeping our “external ghost trick” in mind), will give

$$
Z_{3h}^{-1} Z_{3}^{-1} Z_{3h}^\alpha = 1 + \alpha_s \left( \frac{k}{2} z_2 + \frac{l}{2} z_3 + \frac{m}{2} z_{3h} \right) + O(\alpha_s^2)
$$

$$
= 1 + \frac{k}{2}(Z_2 - 1) + \frac{l}{2}(Z_3 - 1) + \frac{m}{2}(Z_{3h} - 1) + O(\alpha_s^2) .
$$

\(^\text{12}\)The gauge term $\sim k^\mu k^\nu$ does not contribute in the gauge invariant final result. There will be a finite correction $\sim k^2$ to the gluon propagator, for the photon called Cemailing term, important for the Lamb shift. However, in $\overline{\text{MS}}$ we do not subtract finite terms, except for the artifacts of regularization.
This factor multiplied with the NLO and counterterm amplitudes gives no new contributions at NLO, as it is $1 + \mathcal{O}(\alpha_s)$. But multiplied with the LO amplitudes we get the $\mathcal{O}(\alpha_s)$ part of (4.54) as new contribution. The end result of all this is, that for each external line we get into the sum a factor $-(Z_i - 1)$ from the two-point counterterm and a factor $(Z_i - 1)/2$ from the redefinition of the fields, which gives a total of $-(Z_i - 1)/2$. This is exactly $1/2$ of what we got for inserting counterterms at a propagator! But then a propagator has two ends, so if we associate $1/2$ of the counterterm contribution with each end, we have the following simple effective rule: for each LO vertex, we take the factor $Z_i - 1$ of the corresponding counterterm vertex and add factors $-(Z_i - 1)/2$ of the corresponding counterterm two-point interactions for each of the (three or four) attached legs. Then we sum the results for all LO vertices and get a factor, which times the sum of the LO amplitudes is equal to the total sum of counterterm amplitudes, including the effect of external field renormalization. Perhaps it is easier to describe this in a pictorial fashion, as in Fig. 4.4 for a quark-gluon vertex. Note that previous removal of the mass divergencies with the $Z_m$ counterterms is always implied.

![Diagram](image)

Figure 4.4: Effective counterterm contributions to be summed for the renormalization of the quark-gluon vertex. An example configuration is shown, where both quark lines are external and the gluon internal. The (crossed) circles indicate the contributions from Tab. 4.1, and the empty circle means mass renormalization with $Z_m$ has been done previously. The gray ovals indicate the wave functions and the dotted line splits the internal contribution.

We can go even one step further, by now simply calculating what contribution we get at each vertex\footnote{Remember that we do not consider QED corrections, hence the quark-photon QED vertex is not being renormalized.}:

\[
\begin{align*}
\text{quark-gluon:} & \quad 2 \left( -\frac{Z_2 - 1}{2} \right) - \frac{Z_3 - 1}{2} + Z_{1f} - 1 = Z_g - 1 , \\
\text{quark-photon:} & \quad 2 \left( -\frac{Z_2 - 1}{2} \right) + Z_2 - 1 = 0 ,
\end{align*}
\]
4.2. Renormalization Constants and Scheme Choice

\[ \text{ghost-gluon:} \quad 2 \left( \frac{Z_{gh} - 1}{2} \right) - \frac{Z_3 - 1}{2} + Z_{th} - 1 = Z_g - 1 \] \hspace{1cm} (4.55)

\[ \text{3-gluon:} \quad 3 \left( \frac{Z_3 - 1}{2} \right) + Z_1 - 1 = Z_g - 1 , \]

\[ \text{4-gluon:} \quad 4 \left( \frac{Z_3 - 1}{2} \right) + Z_4 - 1 = 2(Z_g - 1) . \]

But actually this means, that we can get the sum of the LO amplitudes and the counterterm amplitudes, by just setting \( g \rightarrow Z_g g_r \) in the sum of bare LO amplitudes! To \( \mathcal{O}(\alpha_s) \) we have \( \mathcal{O}(\alpha_s^2) \), \( g_r^2 \rightarrow [1 + (Z_g - 1)]^k g_r^2 = [1 + k(Z_g - 1) + \mathcal{O}(\alpha_s^2)] g_r^2 \), so we get the LO part from the one and for every vertex a factor \( Z_g - 1 \). As is appropriate, a 4-gluon vertex with \( g^2 \), counts as \( 2(Z_g - 1) \). A quark-photon vertex, which has no power of \( g \), does not add a factor. Finally, since the contribution to the cross section of the counterterms comes from the interference of the LO amplitudes with counterterm amplitudes, we derive the following effective formula for renormalizing the NLO cross section:

\[ d\hat{\sigma}^{(1)} = d\hat{\sigma}^{(1)} + 2k(Z_g - 1)d\hat{\sigma}^{(0)} , \] \hspace{1cm} (4.56)

where \( k \) is the power of the strong coupling constant in the LO cross section \( d\hat{\sigma}^{(0)} \sim \alpha_s^k \sim g_r^{2k} \), and mass renormalization has to be performed first.

Basically we have proven painstakingly this way, that we only need to renormalize the coupling and the masses of the cross section. Then (4.56) just follows from the fact, that a change in the coupling \( g \rightarrow Z_g g_r \) has to be compensated at the order we are considering, since the cross section is a renormalization group invariant. So for the cross sections all our detailed scheme choices are superfluous, except for the \( Z_m \) in (4.46) and (4.48), the \( Z_g \) in (4.25) and the statement that we respect the Slavnov-Taylor identities (4.13) with our scheme. But of course knowing all the renormalization constants allows checks on the amplitude level, so we can test whether the singularities coming from a particular loop are cured by the appropriate counterterm. In addition, the explicit derivation of \( Z_g \) and \( Z_m \) showed in detail the physical content of our choices. Nevertheless, (4.56) is a convenient master formula for renormalization, in particular if we want to change to a different scheme. Finally, it should be mentioned that we have not derived a RGE for the mass as we did for the coupling (4.30). The simple reason is, that of course the heavy quark mass does not run, as we have renormalized it on-shell. It is easy to check this by explicit calculation. On the other hand, the light quark masses do “run” in principle, but as they start with zero mass at \( \mu_0 \), they stay at zero mass. So effectively, all the masses have constant values independent of the renormalization scale.
Chapter 5

Real Contributions

5.1 2 → 3 Phase-Space and Singularities

The processes under consideration here are one-particle-inclusive, which means that only one outgoing particle, an open heavy (anti)quark state, is observed. Thus we lose all information about the other particles involved in the hard subprocess, except for what we can conclude from the conservation laws. In particular we do not know the number of other particles involved and the four momentum of each. Since we are only considering NLO here, i.e., only one additional power of $\alpha_s$, it is obvious that compared to the tree graphs we can at most produce one additional particle. Thus at NLO we need to consider 2 → 3 graphs, which mutually interfere, but of course will be added incoherently to the 2 → 2 LO and NLO virtual contributions of Chap. 2 and Chap. 3, respectively. See Fig. 5.1 for a graphical representation of the structure of the contributions including the general naming scheme for the momenta. The 2 → 3 “real contributions”, so-called because they involve the production of a (quasi-)real particle, have to be integrated over the appropriate 2 → 3 phase-space. In particular the unknown four momentum of the additional particle has to be integrated out. It is in this integration that singularities will arise when the additional particle sets the denominator of an internal propagator to zero.
In order to see this more clearly, let us calculate two simple sub-diagrams occurring in the calculation, displayed in Fig. 5.2.

![Diagrams](image)

Figure 5.2: Two examples of $1 \to 2$ sub-diagrams occurring in the real NLO graphs. The full $2 \to 3$ process is decomposed in a $2 \to 2$ process followed by a $1 \to 2$ decay, examples of the latter are shown here.

We will formally treat the $2 \to 3$ process as a $2 \to 2$ process, with one of the three outgoing particles and a pseudo-particle as products, followed by a $1 \to 2$ decay of the pseudo-particle to the other two outgoing particles. We only observe one outgoing particle and we will stay in the c.m.s. of those two outgoing particles which are not observed, i.e., whose momenta have to be integrated over\(^1\). We chose the two outgoing particles of Fig. 5.2 with the momenta $k_3$ and $p_1$ as unobserved decay products of the pseudo-particle. Thus the $1 \to 2$ decay proceeds in the “laboratory” frame, the c.m.s. of the unobserved decay products, and we keep the momentum of the pseudo-particle $p$ unspecified for now. It will be integrated out later. To simplify the phase-space integration further, we can chose to align the $z$-axis with one of the other three momenta $k_1$, $k_2$ and $p_2$, which will result in three distinct parametrizations. Here we will align the $z$-axis with the incoming momentum of the sub-diagram examples in Fig. 5.2, $k_2$, a choice called “set one” below. The parametrization used for the $n$-dimensional vectors occurring in Fig. 5.2 is then

$$
\begin{align*}
p_1 &= (E_1, p_1^\parallel, -\omega_3 \sin \theta_1 \cos \theta_2, -\omega_3 \cos \theta_1, \hat{p}_1^\parallel), \\
k_3 &= (\omega_3, -p_1^\parallel, \omega_3 \sin \theta_2, \omega_3 \cos \theta_1, -\hat{p}_1^\parallel), \\
k_2 &= (\omega_2, 0, 0, \omega_2, 0) \,.
\end{align*}
\tag{5.1}
$$

Here the “hat” momenta symbolize the $n - 4$ additional components introduced in dimensional regularization. So we get for the $1 \to 2$ decays of Fig. 5.2 with pseudo-particle momentum $p \equiv k_3 + p_1 = (p, 0, 0, 0, 0)$

$$
1 \to 2 = \int d^n k_3 \ d^n p_1 \ \delta(k_3^2) \Theta(\omega_3) \delta(p_1^2 - m^2) \Theta(E_1) \delta^{(n)}(p - k_3 - p_1) \\
= \int d^n p_1 \ \delta(p^2 - 2pE_1 + m^2) \Theta(p - E_1) \delta(p_1^2 - m^2) \Theta(E_1) \\
= \frac{\pi^{\frac{n+1}{2}}}{\Gamma\left(\frac{n+1}{2}\right)} \frac{\omega_3^2}{2p} \int_0^\pi d\theta_1 \, d\theta_2 \, \sin^2 \theta_1 \sin \theta_2 \int_0^{\hat{p}_1^\parallel} d\hat{p}_1^\parallel \frac{\hat{p}_1^\parallel \omega_3 \sin \theta_1 \sin \theta_2}{\sqrt{\left(p_1^2 - m^2\right)^2 \sin^2 \theta_1 \sin^2 \theta_2 - \hat{p}_1^\parallel^2}}.
$$

\(^1\)In the following the Gottfried-Jackson frame [55] is introduced. Similar phase-space calculations appear in [56, 44], but the hat momenta are only treated here. Our notation follows Appendix B of [44].
\[
\frac{\pi^{\frac{n-4}{2}} \Gamma \left( \frac{n}{2} - 1 \right) (p^2 - m^2)^{n-3}}{4 \frac{\Gamma(n-3)}{(p^2)^{\frac{n}{2}-1}}} \int d\Omega_{n-4} \mathcal{I}.
\]

(5.2)

In the third step we have integrated over the \(x\)-components. This implies that the matrix elements to be integrated do not depend on these components. Thus we must later chose the momentum of the observed particle, \(p_2\), to lie in the \(y - z\) plane, which is always possible. Furthermore we have used

\[
d^{n-4}p_1 = \frac{\pi^{\frac{n-4}{2}}}{\Gamma \left( \frac{n}{2} - 1 \right)} (p_1^2)^{\frac{n-6}{2}} dp_1^2,
\]

(5.3)

\[
p_{1_{\text{max}}}^2 = \frac{(p^2 - m^2)^2}{4p^2} \sin^2 \theta_1 \sin^2 \theta_2,
\]

and defined

\[
\int d\Omega_{n-4} \equiv \int_0^\pi d\theta_1 d\theta_2 \sin^{n-3} \theta_1 \sin^{n-4} \theta_2,
\]

(5.4)

\[
\mathcal{I} \equiv \frac{1}{B \left( \frac{n}{2} - 1 \right)} \int_0^1 dx \frac{x^{\frac{n}{2}-3}}{\sqrt{1-x}},
\]

(5.5)

\[
x \equiv \frac{p_1^2}{p_{1_{\text{max}}}^2} = \frac{4(s_4 + m^2)p_1^2}{s_4^2 \sin^2 \theta_1 \sin^2 \theta_2},
\]

(5.6)

where \(s_4 \equiv (k_3 + p_1)^2 - m^2 = p^2 - m^2\) and \(B(v, w)\) is the Euler Beta function. Note that the integral-operator \(\mathcal{I}\) is normalized in the sense that for those parts of the matrix element independent of hat momenta we have \(\mathcal{I} \cdot 1 = 1\). We will postpone the discussion of the hat momenta and continue here by setting that integration to one, i.e., by not considering hat momenta.

Now \(p^2 = 2\omega_3(E_1 + \omega_3) + m^2 \geq m^2\), as is evident from \(k_3^2 = 0\) and \(p_1^2 = m^2\). So the variable \(s_4\) introduced below (5.6) is positive \(s_4 \geq 0\), and \(s_4 \to 0\) when the additional massless particle emission becomes infrared, i.e., \(\omega_3 \to 0\). In (5.2), we find a term \((p^2 - m^2)^{1+\varepsilon} = s_4^{1+\varepsilon}\) with \(n = 4 + \varepsilon\). On the other hand the gluon emission in Fig. 5.2 (a) leads to a massive fermion propagator with momentum \(k_3 + p_1\), so upon integrating over the momentum of the pseudo-particle later in the \(2 \to 3\) phase space, the square of that particular amplitude will lead to terms of the following form

\[
\int ds_4 s_4^{1+\varepsilon} \left[ \frac{1}{(k_3 + p_1)^2 - m^2} \right]^2 = \int ds_4 s_4^{-1+\varepsilon} \frac{\omega_3 - \theta}{\varepsilon - \theta} \infty.
\]

(5.7)

This means we have found an IR singularity! It is regularized by our shift to \(4 + \varepsilon\) dimensions. We can make this explicit by introducing a \(\Delta\)-distribution\(^2\) corresponding to

\(^2\)If \(v \equiv 1 + t_1/s\) and \(w \equiv -u_1/s + t_1\) are introduced, then \(s_4 \to 0\) poles show up for \(w \to 1\), i.e., \(1/s_4 \to 1/(1 - w)\). The singular \(w \to 1\) behavior can then be treated with the usual \(+\)-distribution \(1/(1 - w)_+\) [56].
cutting off the $s_4$-divergence:
\[
\int_0^\Delta ds_4 \frac{f(s_4)}{\mu_4} \left[ g(s_4) \right] + \int_0^\Delta ds_4 \left[ f(s_4) - f(0) \right] g(s_4),
\]
where $g(s_4)$ is singular and $f(s_4)$ is finite for $s_4 \to 0$. Then we can write the following identity
\[
s_4^{-1+\varepsilon} = \frac{\Delta^\varepsilon}{\varepsilon} \delta(s_4) + \left[ s_4^{-1+\varepsilon} \right]_{\Delta}.
\]

For this reason, those squared matrix elements that have a $1/s_4^2$ dependence will lead to infrared $1/\varepsilon$ poles. These poles will cancel the $1/\varepsilon$ IR poles of the virtual contributions in accordance with the Bloch-Nordsieck and Kinoshita-Lee-Nauenberg theorems \[70\].

In Fig. 5.2 (b) we encounter a propagator with the denominator $t' \equiv (k_2 - k_3)^2 = -2\omega_2\omega_3(1 - \cos \theta_1)$. We immediately see the potential for an infrared divergence when $\omega_3 \to 0$. But for the moment let us assume that the phase-space integration is infrared finite, i.e., we are looking at a term in the squared matrix element which does not introduce a second $\omega_3$ in the denominator. What about the angular dependence? We see in (5.1) that for $\theta_1 \to 0$ the momenta $k_2$ and $k_3$ can become collinear, both pointing along the $z$-axis\(^3\). The propagator with $t'$ will lead to following terms in the phase-space integration
\[
\int d\Omega_{n=4} \frac{1}{t'} \sim \int d\Omega_{n=4} \frac{1}{(1 - \cos \theta_1)^j} = \frac{2^{(2-j)\pi}}{n - 4} \Gamma \left( \frac{n - 2(1 + j)}{2} \right) \Gamma(n - (2 + j)).
\]

Obviously, for $j = 1$ and $n = 4 + \varepsilon$ one again gets a $1/\varepsilon$ pole, a collinear one. If we had given $k_2$ a mass, then the integral in (5.10) would become finite for $j = 1$. A singularity would occur in the limit of this mass going to zero. For this reason the collinear singularities are also often called mass singularities. They are absorbed by a redefinition of the parton densities in the so-called mass factorization procedure, as will be shown in Chap. 6. As a final point we note that it is of course possible that a second $\omega_3$ is introduced into the denominator with $j = 1$, for example from the the interference of sub-diagrams (a) and (b) of Fig. 5.2. Then we will get an infrared and collinear pole at the same time, leading to $1/\varepsilon^2$ poles. These will also be canceled against virtual double poles according to the theorems \[70\] mentioned above.

Now we will calculate the full $2 \to 3$ phase-space. First to complete the kinematical parametrization, we will place $p_2$ in the $y-z$ plane, as discussed below (5.2), and $k_1$ then follows from momentum conservation $k_1 + k_2 = p_1 + p_2 + k_3$

\[
p_2 = \left( E_2, 0, |p_2| \sin \Psi, |p_2| \cos \Psi, 0 \right),
\]
\[
k_1 = \left( \omega_1, 0, |p_2| \sin \Psi, |p_2| \cos \Psi - \omega_2, 0 \right).
\]

\(^3\)The $x$- and hat-space components are integrated over in the phase space, so they can become zero.
Chapter 5. Real Contributions

Remembering the definitions of the $2 \to 2$ variables (2.18), which with this choice do not contain the $\theta_1$, $\theta_2$ angles, and adding the c.m.s. momenta variable $s_4$, we have

$$s \equiv (k_1 + k_2)^2 = (\omega_1 + \omega_2)^2 - |p_2|^2,$$
$$t_1 \equiv (k_2 - p_2)^2 - m^2 = 2\omega_2(p_2^1 \cos \Psi - E_2),$$
$$u_1 \equiv (k_1 - p_2)^2 - m^2 = -\omega_2^2 - m^2 + (\omega_1 - E_2)^2,$$
$$s_4 \equiv (k_3 + p_1)^2 - m^2 = 2\omega_3(E_1 + \omega_3) = s + t_1 + u_1.$$  

(5.12)

By using the non-trivial squared momenta and energy-momentum conservation, we find

$$k_1^2 \equiv 0 = \omega_1^2 - (|p_2|^2 - 2|p_2|\omega_2 \cos \Psi + \omega_2^2),$$
$$p_2^1 \equiv m^2 = E_2^2 - |p_2|^2,$$  

$$\omega_1 + \omega_2 \equiv E_1 + E_2 + \omega_3.$$  

(5.13)

Then we can solve towards three arbitrary independent variables, e.g.,

$$\omega_2 = \frac{s + t_1}{2\sqrt{s_4 + m^2}}, \quad |p_2|^2 = \frac{(t_1 + u_1)^2 - 4m^2s}{2\sqrt{s_4 + m^2}},$$
$$\cos \Psi = \frac{t_1s_4 - s(u_1 + 2m^2)}{(s + t_1)(t_1 + u_1)^2 - 4m^2s}.$$  

(5.14)

The remaining variables $\omega_1$, $\omega_3$, $E_1$, $E_2$ immediately follow from (5.13). So together with $\theta_1, \theta_2$ we find five independent variables, as it should be for three independent four-vectors with three mass and four energy-momentum constraints.

We can now write down the the $2 \to 3$ phase-space $d\Omega_3$

$$\int d\Omega_3 = \int d^n p_1 d^n p_2 d^n k_3 \frac{1}{(2\pi)^{n-1}} \frac{1}{(2\pi)^{n-1}} \frac{1}{(2\pi)^{n-1}} \delta(k_3^2)\delta(\omega_3)\delta(p_1^2 - m^2)\delta(p_2^2 - m^2)\Theta(E_1)\Theta(E_2)$$

$$\cdot (2\pi)^{n} \delta^{(n)}(k_1 + k_2 - k_3 - p_1 - p_2)$$

$$= \frac{1}{(2\pi)^{2n-3}} \int d^n p \ d^n p_2 \ \delta(|p_2|^2 - m^2)\Theta(E_2)\delta^{(n)}(k_1 + k_2 - p - p_2) \cdot (1 \to 2)$$

$$= \frac{\pi^{\frac{n}{2}}}{4} \Gamma \left(\frac{n}{2} - 1\right) \frac{1}{(n-3) (2\pi)^{2n-3}} \int d^n p_2 \ \delta(|p_2|^2 - m^2)\Theta(E_2) \frac{s_4^{n-3}}{(s_4 + m^2)^{\frac{n}{2}-1}} \int d\Omega_{n-4} I$$  

(5.15)

where we have split the $2 \to 3$ process into a $2 \to 2$ process with a pseudo-particle of four-momentum $p$, which subsequently decays in a $1 \to 2$ process. That way we are able to use (5.2). After the integration over $p$ in (5.15) any frame can be used for the remaining $2 \to 2$ integration with the pseudo-particle. The c.m.s. is advantageous and we chose

$$k_{1,2} = \frac{\sqrt{s}}{4}(1, 0, 0, \pm 1, 0), \quad p_2 = (E_2, 0, |p_2| \sin \xi, |p_2| \cos \xi, \hat{0}).$$  

(5.16)

From $k_3^2 \equiv 0$ we know that $(p_1^2)^2 + p_2^1 = \omega_3^2 \sin^2 \theta_1 \sin^2 \theta_2$. 

\[\]
Then (5.15) becomes
\[
\int d\mathbf{P}_3 = \frac{2}{(4\pi)^n} \frac{1}{\Gamma(n-3)} \int dE_2 (E_2^2 - m^2) \mathcal{H}^3 \Theta(E_2) \cdot \int_0^\infty \sin^{n-3} \xi \frac{s_4^{n-3}}{(s_4 + m^2)^{\frac{n}{2} - 1}} \int d\Omega_{n-4} \mathcal{I} . \tag{5.17}
\]
Using \( \sqrt{E_2 - m^2} \sin \xi = \sqrt{t_1 u_1 - m^2 s} / \sqrt{s} \) and \( dE_2 d\xi = dt_1 d\xi_1 / (2 \sqrt{s} \sqrt{t_1 u_1 - m^2 s}) \), we arrive at the final result
\[
d\mathbf{P}_3 = \frac{1}{(4\pi)^n \Gamma(n-3) s} \left( \frac{t_1 u_1 - m^2 s}{s} \right) \mathcal{H}^4 \frac{s_4^{n-3}}{(s_4 + m^2)^{\frac{n}{2} - 1}} \int d\Omega_{n-4} \mathcal{I} . \tag{5.18}
\]
For the double differential real cross section, the flux factor \( 1 / (2 s) \) is introduced. Also an auxiliary mass parameter \( \mu^{(4-n)/2} \) for every power of the gauge coupling has to be multiplied, so that the gauge coupling stays dimensionless in \( n \) dimensions. The final result to be used for the NLO real \( 2 \to 3 \) cross sections is then with \( n = 4 + \varepsilon \):
\[
\frac{d^2 \sigma^{(1)}_{2 \to 3}}{dt_1 dt_2} = F_c G_c \int d\Omega_2 \mathcal{I} |\tilde{M}_R|^2 , \tag{5.19}
\]
\[
G_c = \frac{\mu^{-\varepsilon}}{2\pi (4\pi)^{2\varepsilon} \Gamma(1 + \varepsilon)} \frac{s_4^{1+\varepsilon}}{(s_4 + m^2)^{1+\varepsilon}} , \tag{5.20}
\]
where \( F_c \) is given in (2.25) and \( G_c \) parametrizes the difference to the LO cross section, as compared to (2.24).

## 5.2 Partial Fractioning of Angular Integrals

Now we should complete the set of kinematical invariants occurring in the matrix elements by writing down those depending on the angles \( \theta_1, \theta_2 \). We define in addition to (5.12)
\[
\begin{align*}
s_3 &= (k_3 + p_2)^2 - m^2 , \quad s_5 = (p_1 + p_2)^2 = -u_5 , \quad t' = (k_2 - k_3)^2 , \\
u' &= (k_1 - k_3)^2 , \quad u_6 = (k_2 - p_1)^2 - m^2 , \quad u_7 = (k_1 - p_1)^2 - m^2 . \tag{5.21}
\end{align*}
\]
Since they represent only the two angular degrees of freedom, we can find four independent relations between them, e.g.,
\[
\begin{align*}
u' &= -s - u_1 - u_7 , \quad t' = -s - t_1 - u_6 , \\
u_5 &= t_1 + u_1 + s_3 , \quad s_3 = s + u_6 + u_7 . \tag{5.22}
\end{align*}
\]
Furthermore we see that, for example, \( u_7 \) would be identical to \( t_1 \) in \( 2 \to 2 \) kinematics with \( k_1 + k_2 = p_1 + p_2 \). Thus in the infrared limit, \( \omega_3 \to 0 \), or equivalently \( s_4 \to 0 \), we
\[
\begin{array}{|c|c|c|c|c|}
\hline
& \text{set} & a \text{ or } A & b \text{ or } B & C & \text{coll.} \\
\hline
s_3 & I & r_6 & r_3 & r_5 & \\
\hline
s_3 & II & \uparrow \text{ with } t_1 \leftrightarrow u_1 & \uparrow & & \\
\hline
\ell' & I & r_1 & -r_1 & & \checkmark \\
\hline
\ell' & II & \uparrow \text{ with } t_1 \leftrightarrow u_1 & \uparrow & & \checkmark \\
\hline
\ell' & I & r_1(t_1 \leftrightarrow u_1) & r_4 & -r_5 & \checkmark \\
\hline
\ell' & II & \uparrow \text{ with } t_1 \leftrightarrow u_1 & \uparrow & & \checkmark \\
\hline
u_5 & I & r_7 & r_3 & r_5 & \\
\hline
u_5 & II & \uparrow \text{ with } t_1 \leftrightarrow u_1 & \uparrow & & \\
\hline
u_6 & I & r_2 & r_1 & & \\
\hline
u_6 & II & \uparrow \text{ with } t_1 \leftrightarrow u_1 & \uparrow & & \\
\hline
u_7 & I & r_2(t_1 \leftrightarrow u_1) & -r_4 & r_5 & \\
\hline
u_7 & II & \uparrow \text{ with } t_1 \leftrightarrow u_1 & \uparrow & & \\
\hline
\end{array}
\]

Table 5.1: The \(\theta_1, \theta_2\)-coefficients according to (5.25) for the angular Mandelstam variables (5.21). For brevity, (5.23), (5.24) and (5.26) have been employed. Results for “set one” and “set two” with \(k_2\) and \(k_1\) aligned with the \(z\)-axis, respectively, are shown. It is indicated which variables can develop a collinear divergence, see Sec. 5.3. \(\uparrow\ldots\uparrow\) symbols mean inserting the columns of the row above changed as indicated.

find \(u_7 \to t_1\). On the other hand \(s_3\) will simply vanish in that limit. For the invariants of (5.21) we can write

\[
s_3 = s_4 s_3, \quad \ell' = s_4 \ell', \quad \ell' = s_3 \ell', \\
u_5 = -s + s_4 u_5, \quad u_6 = u_1 + s_4 u_6, \quad u_7 = t_1 + s_4 u_7,
\]

where the underlined quantities are dimensionless and become finite functions of the \(2 \to 2\) Mandelstam variables (5.12) and \(m^2\) in the \(s_4 \to 0\) limit.

The angular variables (5.21) all have one of the following two structures

\[
[ab] \sim a + b \cos \theta_1 \quad \text{or} \quad [ABC] \sim A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2,
\]

and we will symbolize the angle independent variables of (5.12) as \([\cdot]\). Whether an angular variable is of \([ab]\) or \([ABC]\) type depends on the chosen parametrization. In our calculation we really only need the “set one” parametrization given above. A “set two”
5.2. Partial Fractioning of Angular Integrals

parametrization can be helpful at times, however. Compared to (5.1) and (5.11), we align
\( k_1 \) with the \( z \)-axis and adjust \( k_2 \), so that all other momenta stay untouched. Then in
(5.14) in the \( \cos \Psi \) we get a \( t_1 \leftrightarrow u_1 \) crossing and no other changes. The third possibility
of putting \( p_2 \) on the \( z \)-axis is not employed by us. In Tab. 5.1 we have collected the
angular coefficients in terms of the \([\cdot]\) variables for both sets of parametrizations. We
have used the following abbreviations

\[
\begin{align*}
  r_1 &= -\frac{s + t_1}{2(s_4 + m^2)}, & r_2 &= -\frac{s_4 + u_1 + 2m^2}{2(s_4 + m^2)}, & r_3 &= \frac{2m^2 s - s_4 t_1 + su_1}{2(s_4 + m^2)}, \\
  r_4 &= -\frac{s(s_4 + m^2) + m^2 s - t_1 u_1}{2(s_4 + m^2)}, & r_5 &= -\frac{\sqrt{s(s_4 + m^2)(t_1 u_1 - m^2 s)}}{(s_4 + m^2)}, \\
  r_6 &= -\frac{t_1 + u_1 + 2m^2}{2(s_4 + m^2)}, & r_7 &= \frac{s + s_4}{2(s_4 + m^2)}. 
\end{align*}
\]

(5.26)

The variables in Tab. 5.1 have been grouped so that one can easily see the effects of
switching between the sets: on one hand there is \( t_1 \leftrightarrow u_1 \) crossing, on the other hand the
pairs \( t', u' \) and \( u_6, u_7 \) exchange their role as \([ab]\) and \([ABC]\) variables.

Let us quickly return to the question of hat momenta. We noted already concerning
(5.5) that \( \mathcal{I} \cdot 1 = 1 \). Squares of hat momenta occur always linearly in the squared matrix
elements, so we need to look at

\[
\mathcal{I} \cdot \hat{p}_1^2 = \frac{s_4^2 \sin^2 \theta_1 \sin^2 \theta_2}{4(s_4 + m^2)} B \left( \frac{1}{2}, \frac{n-1}{2} \right) \int_0^1 dx \frac{x^{n-2}}{\sqrt{1-x}} \\
= \frac{n - 4 s_4^2 \sin^2 \theta_1 \sin^2 \theta_2}{n - 3} = \frac{\varepsilon}{4(s_4 + m^2)} + \mathcal{O}(\varepsilon^2).
\]

(5.27)

In the squared matrix elements at worst a \( 1/s_4^2 \) can appear, since in the amplitudes
omitting one real particle can result in only one infrared divergent propagator. From
(5.27) and (5.19) we get for a \( 1/s_4^2 \) hat term a factor of \( s_4^{1+\varepsilon}/(s_4 + m^2)^{2+\varepsilon/2} \), which is
obviously infrared \( s_4 \rightarrow 0 \) safe. Thus we will not get infrared divergencies from the hat
terms, no \( 1/\varepsilon^2 \) poles are possible and the expansion to \( \mathcal{O}(\varepsilon) \) in (5.27) is justified. Note that
for \( m \rightarrow 0 \) we would get an infrared divergence, i.e., the mass acts as an infrared
regulator here. Concerning collinear divergencies stemming from terms like (5.10), we note again
that only one propagator can become collinearly divergent by the emission of one real
particle in the amplitude, so that \( j = 1 \) or \( j = 2 \). The sines of (5.27) when inserted into
(5.10), basically shift \( n \rightarrow n + 2 \). Then for \( j = 1 \) we will obtain no divergence. But \( j = 2 \)
in (5.10) gives \( 2\pi/(n-6) \) which yields a \( 1/\varepsilon \) pole for this shift. In this case the \( \varepsilon \) factor of
(5.27) will be canceled and a finite contribution at \( \mathcal{O}(1) \) exists. This means, that in our
calculation the only hat terms we have to keep are those having a double collinear form,
i.e., with \( 1/t^2 \) or \( 1/u'^2 \), the others can be dropped.

As we have seen, the variables (5.21) have either the \([ab]\) or the \([ABC]\) form of (5.25).
In the matrix elements, various complicated combinations of those variables can occur. It
is impossible to directly perform the angular integrations over them, in particular not in \( n \) dimensions. But it turns out to be possible to reduce all of the integrals to the following standard form

\[
I^{(k,l)} = \int d\Omega_{\mathbf{r}} (a + b \cos \theta_1)^{-k} (A + B \cos \theta_1 + C \cos \theta_2)^{-l},
\]

i.e., an angular integration with (5.4) and an \([ab]\) variable to the power \( k \) and an \([ABC]\) variable to the power \( l \) in the denominator. We also set \( n = 4 + \varepsilon \) here and in the remainder of the chapter. How can one obtain such a form from expressions like \((t_{11} u_{12} / s_{11} u_{12})^2\) occurring in the squared matrix elements? The trick is to use Mandelstam relations like (5.22) for partial fractioning. These expressions are of the type

\[
e^{[ABC]} = f[\cdot] + g[ab] + h[ABC].
\]

Since \([\cdot]\) variables can be factored out of the angular expressions, we only have to worry about terms with \( e, g, \) and \( h \). Also expressions with only powers of \( e \) and \( g \) or \( g \) and \( h \) in the denominator already comply with the (5.28) form. So the only terms we have to look at are combinations of all three \( e, g, \) and \( h \) or of only \( e \) and \( h \), i.e., those cases that have two \([ABC]\) variables.

Starting with the combinations of all three variables, we have

\[
\begin{align*}
\frac{1}{egh} &= f \left( \frac{1}{gh} - \frac{1}{eg} - \frac{1}{eh} \right), \\
\frac{e}{gh} &= \frac{1}{g} + \frac{1}{h} + \frac{f}{gh}, \\
\frac{g}{eh} &= \frac{1}{h} - \frac{1}{e} - \frac{f}{eh}, \\
\frac{h}{eg} &= \frac{1}{g} - \frac{1}{e} - \frac{f}{eg}, \\
\frac{eg}{h} &= g + \frac{fg}{h} + \frac{g^2}{h}, \\
\frac{gh}{e} &= g - \frac{fg}{e} - \frac{g^2}{e},
\end{align*}
\]

In order to rewrite the combinations of two variables, we use the fact that \([\cdot] + [ab] \rightarrow [ab].\) So with

\[
g_f[ab] \equiv f[\cdot] + g[ab] \quad \Rightarrow \quad e^{[ABC]} = g_f[ab] + h[ABC],
\]

terms with only powers of \( e, g_f \) or \( g_f, h \) in the denominator also comply with the (5.28) form. Then

\[
\begin{align*}
\frac{1}{eh} &= \frac{1}{g_fh} - \frac{1}{g_fe}, \\
\frac{e}{h} &= 1 + \frac{g_f}{h}, \\
\frac{h}{e} &= 1 - \frac{g_f}{e}, \\
eh &= g_fh + h^2.
\end{align*}
\]

Equations of the form \([ab], [ABC] = [\cdot] + [\cdot] + [ab], [ABC]\) can also be treated by (5.32). Powers of the variables can be treated by repeated application of these rules, for example

\[
\frac{gh^2}{e^2} = \frac{gh}{e^2} - \frac{fg}{e} - \frac{g^2}{e^2} = g - \frac{2fg}{e} - \frac{2g^2}{e^2} + \frac{fg^2}{e^2} + \frac{g^3}{e^2}.
\]
So we can find, e.g., the appropriate expressions for \( u_6 u_7^2/s_3^2 \), complying with (5.28), by setting \( \{e, f, g, h\} \rightarrow \{s_3, s, u_6, u_7\} \) in (5.33). If we have for example \( 1/(s_3 u_7) \), then the first relation of (5.32) tells us that we need to introduce the auxiliary variable \( u_{6s} = s + u_6 \) to write the result in the desired form.

Our goal is to eliminate all occurrences of two \([ABC]\) variables. As we see from the example (5.33), repeated application of the appropriate rules (5.30) and (5.32) will achieve this aim. In order to automate this procedure in a Mathematica [57] program, one has to chose a complete set of relations like (5.22) in order to eliminate all such terms:

\[
\begin{align*}
    u' &= -s - u_1 - u_7, \\
    u_5 &= u_1 - t' + u_7, \\
    s_3 &= -t_1 - t' + u_7, \\
    u_5 &= t_1 + u_1 + s_3, \\
    t' &= -s - t_1 - u_6.
\end{align*}
\]

(5.34)

Though using this completely computerized method of obtaining standard form integrals has the advantage of producing error free results quickly, it has the disadvantage of often yielding unnecessarily complicated expressions. For example

\[
\frac{1}{(s_3 u')^2} \frac{1}{u_5^2(t_1 + u_6)^3} + \frac{1}{u_6^2(t_1 + u_6)^2} + \frac{1}{u^2(t_1 + u_6)^2} + \frac{2}{u'(t_1 + u_6)^3},
\]

whereas the original expression \( 1/(s_3 u')^2 \) is already in the standard form (5.28) if we use “set one” instead. In general we have used the automatic partial fractioning using “set one” for the long expressions, where also often cancellations occur upon fractioning, and proceeded term by term using both sets for short expressions, like in the soft \( s_4 \rightarrow 0 \) limits.

### 5.3 Calculation of Basic Angular Integrals

After performing the extensive partial fractioning of the squared matrix elements described in the last section and collecting the terms, what remains to be done is the calculation of the integrals brought to the standard form (5.28):

\[
I_{e}^{(k,l)} = \int_{0}^{\pi} d\theta_1 d\theta_2 \frac{\sin^{1+\epsilon} \theta_1}{(a + b \cos \theta_1)^k} \frac{\sin^\epsilon \theta_2}{(A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2)^l}.
\]

(5.36)

The first important point to notice is that there are four classes of integrals, depending on the collinear structure. The \([ab]\) and \([ABC]\) variable can both be either “collinear” or not, which yields four combinations. In the case of the \([ab]\) variable, collinearly divergent behavior is possible for \( a^2 = b^2 \), so that \( (a + b \cos \theta_1) \rightarrow a(1 \pm \cos \theta_1) \). Then the zero occurs at the edge of the \( \theta_1 \) integration region and is not integrable. For the \([ABC]\) variable the same comments apply for \( \theta_2 \) when \( A^2 = B^2 + C^2 \). This is more difficult to see due to the more complicated structure including a \( \theta_1 \) dependence. In principle integration over
\( \theta_1 \) will give terms with a \( A^2 - B^2 - C^2 \cos^2 \theta_2 \) dependence, which explicitly shows the appropriate “collinear” behavior. But in practice it is more convenient to integrate out \( \theta_2 \) first, which means that the divergence will be shifted to the \( \theta_1 \) integration. Note that the \( D_{\pm} \)-rotation introduced below demonstrates the similarity of the collinear behavior in \( \theta_1 \) and \( \theta_2 \). Perhaps simple integration examples show the possible collinear poles most clearly: setting \( k = 2, l = 0 \) and \( \varepsilon = 0 \) in (5.36), we get \( 2\pi/(a^2 - b^2) \), whereas \( k = 0, l = 2 \) and \( \varepsilon = 0 \) gives \( 2\pi/(A^2 - B^2 - C^2) \). It has already been pointed out in Tab. 5.1 that the only “collinear” variables in our calculation are \( t' \) and \( u' \).

We shall use the following notation for angular integrals \( I^{(k,l)}_\varepsilon \)

\[
\begin{align*}
\quad a^2 \neq b^2 \quad \text{and} \quad A^2 \neq B^2 + C^2 & \quad \Rightarrow \quad I^{(k,l)}_{\varepsilon,0} , \\
\quad a^2 = b^2 \quad \text{and} \quad A^2 \neq B^2 + C^2 & \quad \Rightarrow \quad I^{(k,l)}_{\varepsilon,a} , \\
\quad a^2 \neq b^2 \quad \text{and} \quad A^2 = B^2 + C^2 & \quad \Rightarrow \quad I^{(k,l)}_{\varepsilon,aA} , \\
\quad a^2 = b^2 \quad \text{and} \quad A^2 = B^2 + C^2 & \quad \Rightarrow \quad I^{(k,l)}_{\varepsilon,aA} .
\end{align*}
\]

\( I_0 \) integrals are finite and so for them we could set \( \varepsilon = 0 \). The others require regularization. Note for the \( I_{aA} \) integrals that when one angular integral is diverging the other is not, as is obvious from \( A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2 \rightarrow A \pm B \neq 0 \) at \( \theta_1 = 0, \pi \), see Tab. 5.1. This means concerning regularization that no double poles \( 1/\varepsilon \cdot 1/\varepsilon \) appear, when performing the angular integrations. Double poles only appear when there is in addition an infrared pole for \( s_4 \rightarrow 0 \). In principle, if one could calculate all integrals keeping the full \( \varepsilon \) dependence, i.e., calculate \( I^{(k,l)}_\varepsilon \) without approximation, one could obtain all results by inserting the conditions (5.37) afterwards. In practice, most of the time it is necessary to split up the integrations according to (5.37) first, so that one calculate the integrals by exploiting the divergence structure.

We wish to calculate the minimal number of integrals necessary. As a first step we will show, that all \( I_A \) integrals can be transformed to \( I_a \) ones. With the unit vector

\[
\bar{e}^T = (\sin \theta_1 \cos \theta_2, \sin \theta_1 \sin \theta_2, \cos \theta_1) , \quad \bar{e}^2 = 1 ,
\]

where \( T \) signifies transposition, we can write the scalars

\[
\begin{align*}
A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2 & = A + (C, 0, B) \cdot \bar{e} , \\
A + b \cos \theta_1 & = a + (0, 0, b) \cdot \bar{e} .
\end{align*}
\]

So the parameter vector of the \([a,b] \) variable points along the \( z \)-axis. Now we use a rotation that puts the parameter vector of the \([ABC] \) variable on the \( z \)-axis [81]:

\[
D_{\pm} = \begin{pmatrix}
\pm \frac{B}{\sqrt{B^2 + C^2}} & 0 & \pm \frac{C}{\sqrt{B^2 + C^2}} \\
0 & 1 & 0 \\
\pm \frac{C}{\sqrt{B^2 + C^2}} & 0 & \pm \frac{B}{\sqrt{B^2 + C^2}}
\end{pmatrix} , \quad D_{\pm}^{-1} = D_{\pm}^T .
\]

\( I_{aA} \) integrals are finite and for them we could set \( \varepsilon = 0 \). The others require regularization. Note for the \( I_{aA} \) integrals that when one angular integral is diverging the other is not, as is obvious from \( A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2 \rightarrow A \pm B \neq 0 \) at \( \theta_1 = 0, \pi \), see Tab. 5.1. This means concerning regularization that no double poles \( 1/\varepsilon \cdot 1/\varepsilon \) appear, when performing the angular integrations. Double poles only appear when there is in addition an infrared pole for \( s_4 \rightarrow 0 \). In principle, if one could calculate all integrals keeping the full \( \varepsilon \) dependence, i.e., calculate \( I^{(k,l)}_\varepsilon \) without approximation, one could obtain all results by inserting the conditions (5.37) afterwards. In practice, most of the time it is necessary to split up the integrations according to (5.37) first, so that one calculate the integrals by exploiting the divergence structure.

We wish to calculate the minimal number of integrals necessary. As a first step we will show, that all \( I_A \) integrals can be transformed to \( I_a \) ones. With the unit vector

\[
\bar{e}^T = (\sin \theta_1 \cos \theta_2, \sin \theta_1 \sin \theta_2, \cos \theta_1) , \quad \bar{e}^2 = 1 ,
\]

where \( T \) signifies transposition, we can write the scalars

\[
\begin{align*}
A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2 & = A + (C, 0, B) \cdot \bar{e} , \\
A + b \cos \theta_1 & = a + (0, 0, b) \cdot \bar{e} .
\end{align*}
\]

So the parameter vector of the \([a,b] \) variable points along the \( z \)-axis. Now we use a rotation that puts the parameter vector of the \([ABC] \) variable on the \( z \)-axis [81]:

\[
D_{\pm} = \begin{pmatrix}
\pm \frac{B}{\sqrt{B^2 + C^2}} & 0 & \pm \frac{C}{\sqrt{B^2 + C^2}} \\
0 & 1 & 0 \\
\pm \frac{C}{\sqrt{B^2 + C^2}} & 0 & \pm \frac{B}{\sqrt{B^2 + C^2}}
\end{pmatrix} , \quad D_{\pm}^{-1} = D_{\pm}^T .
\]
5.3. Calculation of Basic Angular Integrals

Obviously a rotation will simply transform a unit vector to a new one and we have
\[
\vec{e}^{rT} \equiv (\mathcal{D}_\pm \cdot \vec{e})^T = (\sin \theta_1 \cos \theta_2, \sin \theta_1 \sin \theta_2, \cos \theta_1), \quad \vec{e}^{r2} = 1, \quad (5.41)
\]
\[
(C, 0, B) \cdot \mathcal{D}_T^T = (0, 0, \pm \sqrt{B^2 + C^2}), \quad (0, 0, b) \cdot \mathcal{D}_T^\pm = \frac{1}{\sqrt{B^2 + C^2}}(\pm bC, 0, \pm bB).
\]

Now we can rewrite the scalars by inserting a one, which gives
\[
(C, 0, B) \cdot \vec{e} = (C, 0, B) \cdot \mathcal{D}_-^{-1} \cdot \mathcal{D}_- \cdot \vec{e} = (0, 0, \pm \sqrt{B^2 + C^2}) \cdot \vec{e}',
\]
\[(0, 0, b) \cdot \vec{e} = (0, 0, b) \cdot \mathcal{D}_T^{-1} \cdot \mathcal{D}_T \cdot \vec{e} = \frac{1}{\sqrt{B^2 + C^2}}(\pm bC, 0, \pm bB) \cdot \vec{e}'. \quad (5.42)
\]

The integration ranges \(0 \leq \theta_1, \theta_2 \leq \pi\) in (5.38) cover the complete half-space of positive \(y\)-components of \(\vec{e}\). Since the rotation (5.40) leaves the \(y\)-components intact, this remains unchanged by the transformation, i.e., we must have \(0 \leq \theta_1, \theta_2 \leq \pi\), so that the same is true for \(\vec{e}'\). Then we can rewrite (5.36) as
\[
I_{e^{(k,l)}}^{\pm} \rightarrow I_{e^{(l,k)}}^{\pm} \left[ a \leftrightarrow A, \ b \rightarrow \pm \sqrt{B^2 + C^2}, \ B \rightarrow \pm \frac{bB}{\sqrt{B^2 + C^2}}, \ C \rightarrow \pm \frac{bC}{\sqrt{B^2 + C^2}} \right],
\]
\[
= \int_0^\pi d\theta_1 d\theta_2 \frac{\sin^1 \theta_1'}{(A \pm \sqrt{B^2 + C^2} \cos \theta_1')^2} \frac{\sin^1 \theta_2'}{(a \pm \frac{bB}{\sqrt{B^2 + C^2}} \cos \theta_1' \pm \frac{bC}{\sqrt{B^2 + C^2}} \sin \theta_1' \cos \theta_2')^2}.
\quad (5.43)
\]

We see clearly, that an \(I_{A^{(k,l)}}^{\pm}\) integral will directly transform to an \(I_{A^{(l,k)}}^{\pm}\) integral, and vice versa. So in our collection of integral results no \(I_{A^{(k,l)}}^{(l,k)}\) integrals will appear, since they can be directly obtained from the corresponding \(I_{A^{(l,k)}}^{(l,k)}\) results, which are easier to calculate, using the substitutions displayed in (5.43). Note that there is an ambiguity inherent in our definitions of \(I_{a}, I_{A}\) and \(I_{aA}\) concerning the sign of the “collinear” solutions for the variables in (5.37). This ambiguity is of course present when (5.43) is used to relate \(I_{A}\) to \(I_{a}\), since we must choose whether \(\sqrt{B^2 + C^2}\) is \(+A\) or \(-A\). Since in “set one” \(t'\) and in “set two” \(u'\) have \(b = -a\), i.e., the collinear divergence appears for forward emission, we calculate our integrals for \(b = -a\). In particular we will relate \(I_{A}\) to \(I_{a}\) in such a way, that \(a\) becomes \(-b\) after transformation. If we are not deriving general formulae, but already inserting specific variables, we can still get relations from \(\mathcal{D}_\pm\). From (5.26) we have \(r_1 = -\sqrt{r_1^2 + r_2^2}\), and so Tab. 5.1 shows
\[
\mathcal{D}_+ : \quad I_{e^{(k,l)}}^{(k,l)}(t', u') = I_{e^{(k,l)}}^{(l,k)}(t', u')|_{t_1+u_1}, \quad (5.44)
\]
\[
\mathcal{D}_- : \quad I_{e^{(k,l)}}^{(k,l)}(u_6, u_7) = I_{e^{(l,k)}}^{(l,k)}(u_6, u_7)|_{l_1+u_1}. \quad (5.45)
\]

To further reduce the number of integrals that have to be calculated, we can use the technique of differentiating with respect to a parameter. The obvious targets are the
parameters $a, A$, which do not multiply an angular dependence, and we find

$$I_{e}^{(k,l)} = \begin{cases} 
\frac{(-1)^{k-1}}{(k-1)!} \frac{\partial^{k-1}}{\partial a^{k-1}} I_{e}^{(l,1)} & \text{with } a^2 \neq b^2 , \\
\frac{(-1)^{l-1}}{(l-1)!} \frac{\partial^{l-1}}{\partial A^{l-1}} I_{e}^{(k,1)} & \text{with } A^2 \neq B^2 + C^2 , \\
\frac{(-1)^{l-1}}{(l-1)!} \frac{\partial^{l-1}}{\partial A^{l-1}} I_{e}^{(k,1)} & \text{with } A^2 \neq B^2 + C^2 . 
\end{cases}$$

(5.46)

Note that for the parameter differentiation to work properly, we need to assume that the parameters are independent. Hence the collinear cases are excluded.

At this point we can state which basic integrals we need to calculate in order to obtain all other required integrals with the methods explained above. Firstly, those integrals where $l = 0$ and $k \leq 0$ can be performed keeping the complete $\varepsilon$ dependence, so that the $I_{0}$ and $I_{a}$ (and $I_{A}$ using $D_{\pm}$) cases can be easily derived from $I_{e}$ by taking the $\varepsilon \to 0$ and $b^2 \to a^2$ limits. We need $k = -2, -1, 0$. For the non-divergent $I_{0}^{(k,l)}$, the $(k, l)$ combinations $(-1, -1), (1, -3)$ and $(1, 1)$ are needed. For the single collinear $I_{A}^{(k,l)}$, (and thus $I_{e}^{(k,l)}$), the combinations $(1, -2), (1, 0), (1, 1), (2, -2), (2, 0)$ and $(2, 1)$ are necessary. Finally for the double collinear $I_{aA}^{(k,l)}$, we only need $(1, 1)$. So by calculating only $13$ integrals we can reproduce the $29$ integrals of [44] which are needed for the processes.\(^5\) Let us start with the $l = 0, k \leq 0$ cases. They are simple enough to be directly computed with the help of Mathematica [57] or integral tables like [82], yielding

$$I_{e}^{(0,0)} = \frac{2\pi}{1 + \varepsilon} ,$$

(5.47)

$$I_{e}^{(-1,0)} = 2\pi \frac{a}{1 + \varepsilon} ,$$

(5.48)

$$I_{e}^{(-2,0)} = \pi \left[ \frac{2a^2 + b^2}{1 + \varepsilon} - \frac{b^2}{3 + \varepsilon} \right] .$$

(5.49)

Next concerning the non-divergent $I_{0}^{(k,l)}$, we find for those with negative $l$

$$I_{0}^{(1,-1)} = \pi \left[ \frac{2aA + bB}{1 + \varepsilon} - \frac{bB}{3 + \varepsilon} \right] .$$

(5.50)

$$I_{0}^{(1,-3)} = \frac{\pi}{6b^2} \left\{ 4bB(9A^2b^2 - 9aAbB + (3a^2 + b^2)B^2) + 6b(3aAb - 3a^2B \right\} .$$

\(^5\)In [44] there are two additional integrals, $I_{aA}^{(-1,-1)}$ and $I_{aA}^{(-2,-1)}$, not appearing in our decomposition procedure. They can be obtained directly using (5.61) below and App. B.1. Some integrals not found in [44], that do appear in our decomposition, follow from the 13 integrals listed here.
\[ + 2b^2B) C^2 + 3(Ab - aB)(2(Ab - aB)^2 - 3(a^2 - b^2)C^2) \ln \frac{a + b}{a - b} \]

\[ + \frac{\varepsilon}{12} \left\{ 4b(-4B(27A^2b^2 - 27aAbB + (9a^2 + 4b^2)B^2)) + 3(-27aAb \\
+ 27a^2B - 16b^2B)C^2) + (Ab - aB)(9 \ln \frac{a + b}{a - b}) \frac{6(a^2 - b^2)C^2}{a - b} \right. \]

\[ + (2(Ab - aB)^2 - 3(a^2 - b^2)C^2) \ln \frac{a + b}{a - b} + 36(2(Ab - aB)^2 \left. \\
- 3(a^2 - b^2)C^2 \right) \text{Li}_2 \left( \frac{-2b}{a - b} \right) \right\} + \mathcal{O}(\varepsilon^2). \quad (5.51) \]

To obtain these results we have done the \( \theta_2 \) integration part by part as is demonstrated in (5.55) below. In the case of \( J_0^{(1, -3)} \) the \( \theta_1 \) integration gives hypergeometric functions that were expanded using (B.7) and (B.8) and linear transformations. The last finite integral is to \( \mathcal{O}(1) \) given by

\[ I_0^{(1, 1)} = \frac{\pi}{\sqrt{X}} \ln \left( \frac{aA - bB + \sqrt{X}}{aA - bB - \sqrt{X}} \right), \quad (5.52) \]

\[ X = (aA - bB)^2 - (A^2 - B^2 - C^2)(a^2 - b^2), \]

which is obtained by straightforward integration with \( \varepsilon = 0 \).

In the single collinear case, we begin with those integrals having \( l = 0 \). It is easy to perform them directly, and we obtain

\[ I_a^{(1, 0)} = \frac{\pi}{\varepsilon} \frac{2}{a}, \quad (5.53) \]

\[ I_a^{(2, 0)} = -\frac{\pi}{\varepsilon} \frac{2}{a^2} \frac{2 - \varepsilon}{2 - \varepsilon}. \quad (5.54) \]

We note the curious fact, that \( I_a^{(2, 0)} \) is finite for \( \varepsilon \to 0 \), whereas the integral diverges when we set \( \varepsilon = 0 \) before integrating. Actually we used this integral above as a simple divergent example! The situation is exactly like for (3.3). We can transform the integral using \( t = (1 - \cos \theta_1)/2 \) and then introduce a cutoff \( \Lambda \) with \( 0 < \Lambda < 1 \). We find hypergeometric functions and the integration \([\Lambda, 1]\) has to be analytically continued from \( \text{Re} \varepsilon' > 2 \) exactly in such a fashion, that its \( \Lambda \)-dependence cancels against that of the \([0, \Lambda]\) integration, which is unproblematic with \( \text{Re} \varepsilon > -2 \). Using linear transformations of the hypergeometric functions, we find that this is the case for \( \varepsilon' \to \varepsilon \). A finite rest remains which gives (5.54) after the \( \theta_2 \)-integration. Next we treat the \( I_a \) integrals with \( l = -2 \). Here we can expand the \([ABC]\) term and then the \( \theta_2 \)-integration of the parts is easy, resulting in

\[ \int_0^\pi d\theta_2 \sin^\varepsilon \theta_2 (A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2)^2 \]
\[ I_a^{(1,-2)} = \frac{2\pi}{a} \left[ \frac{(A + B)^2}{\varepsilon} - \frac{B^2 + 2AB - C^2}{1 + \varepsilon} - \frac{C^2}{2 + \varepsilon} \right], \quad (5.56) \]

\[ I_a^{(2,-2)} = \frac{2\pi}{a} \left[ \frac{(A + B)^2}{-2 + \varepsilon} + \frac{C^2 - 2B(A + B)}{\varepsilon} + \frac{B^2 - C^2}{1 + \varepsilon} \right]. \quad (5.57) \]

Next let us treat the two remaining cases which have an \([ABC]\) term in the denominator. For \(t'\) we have \(a = -b\) and so the divergence appears with \(1 - \cos \theta_1\) in the denominator. We subtract the \(\cos \theta_1 \to 1\) limit of \(1/(A + B \cos \theta_1 + C \sin \theta_1 \cos \theta_2)\), multiplied by the rest of the kernel, as a counterterm. Then the remaining integral is finite, can be expanded in \(\varepsilon\) prior to integration and is thus easily performed. Adding the integrated counterterm, which is expanded in \(\varepsilon\) only after integration, yields the complete answer. The needed limits are

\[ I_a^{(1,1)} = \frac{1}{A + B}, \quad I_a^{(2,1)} = \frac{1}{A + B} + \frac{B(A + B) + C^2 \cos^2 \theta_2}{(A + B)^3} (1 - \cos \theta_1), \quad (5.58) \]

where a term \(\sim \cos \theta_2\) has been dropped in the latter since it does not contribute. The results are

\[ I_a^{(1,1)} = \frac{\pi}{a(A + B)} \left\{ \frac{2}{\varepsilon} + \ln \left[ \frac{(A + B)^2}{A^2 - B^2 - C^2} \right] + \frac{\varepsilon}{2} \ln^2 \left( \frac{A - \sqrt{B^2 + C^2}}{A + B} \right) \right. \]
\[ - \frac{1}{2} \ln^2 \left( \frac{A + \sqrt{B^2 + C^2}}{A - \sqrt{B^2 + C^2}} \right) + 2 \text{Li}_2 \left( -\frac{B + \sqrt{B^2 + C^2}}{A - \sqrt{B^2 + C^2}} \right) \]
\[ - 2 \text{Li}_2 \left( \frac{B - \sqrt{B^2 + C^2}}{A + B} \right) \left\} + \mathcal{O}(\varepsilon^3), \quad (5.59) \]

\[ I_a^{(2,1)} = \frac{\pi}{a^2(A + B)} \left\{ \frac{B^2 + AB + C^2}{(A + B)^2} \left[ \frac{2}{\varepsilon} + \ln \left[ \frac{(A + B)^2}{A^2 - B^2 - C^2} \right] \right] \right. \]
\[ - \frac{2C^2}{(A + B)^2 - 1} \left\} + \mathcal{O}(\varepsilon). \quad (5.60) \]

The double collinear case occurs in our calculation for \(t'\) and \(u'\). \(t'\) has \(a = -b\) and \(u'\) has \(A = -\sqrt{B^2 + C^2}\) with \(0 \leq -\frac{B}{A} \leq 1\). Then by setting \(\cos \kappa = -\frac{B}{A}\) in the results (A4) and (A11) of [83], we obtain

\[ I_{aA}^{(k,l)} \left[ \begin{array}{c} 0 \leq -\frac{B}{A} \leq 1 \\ 0 \leq \frac{k + l}{2} \leq 1 \end{array} \right] \frac{2\pi}{a^k A^l} \frac{\Gamma(1 + \varepsilon)}{\Gamma(1 + \frac{\varepsilon}{2})^2} B \left( 1 + \frac{\varepsilon}{2} - k, 1 + \frac{\varepsilon}{2} - l \right) \text{F}_1 \left( k, l, 1 + \frac{\varepsilon}{2}; \frac{A - B}{2A} \right). \quad (5.61) \]
which, using a linear transformation of the third result in (B.6), immediately gives

\[
I_{aA}^{(1,1)} = \frac{2\pi}{a(A + B)} \left[ \frac{2}{\varepsilon} + \ln \left( \frac{A + B}{2A} \right) - \frac{\varepsilon}{2} \text{Li}_2 \left( -\frac{A - B}{A + B} \right) \right] + O(\varepsilon^2). \tag{5.62}
\]

This finishes the derivation of basic angular integrals. We will give one quick example of how they are used in practice. In our decomposition procedure we may find a term \( \sim u_6/u' \), with no other angular variables. In set one, \( u' \) is an \([ABC]\) variable and can diverge collinearly, whereas \( u_6 \) is an \([ab]\) variable and cannot diverge collinearly, compare Tab. 5.1. So we need the integral \( I_{a}^{(-1,-1)} \). We can relate this integral to \( I_{a}^{(1,1)} \) by \( D_{\pm} \).

So first we use \( I_{a}^{(1,-1)} = \frac{1}{2a} I_{a}^{(1, -2)} \), compare (5.46) and (5.56), then apply \( D_{+} \) with \( \sqrt{B^2 + C^2} = -A \). We could of course also use \( D_{-} \) with \( \sqrt{B^2 + C^2} = A \) to derive the same general formula, but the former corresponds to \( u' \rightarrow t' \) directly. We get

\[
I_{a}^{(-1,1)} = \frac{\pi(aA - bB)}{A^2} \left[ \frac{2}{\varepsilon} + \frac{2bB(1 + \varepsilon)}{(aA - bB)} \right]. \tag{5.63}
\]

Now we plug in the values from Tab. 5.1 and finally find

\[
I_{a}^{(-1,1)}(u_6, u') = \frac{2\pi(m^2 + s_4)t_1u_1}{s_4(s_4 - t_1)^2} \cdot \left\{ \frac{2}{\varepsilon} + \frac{(1 + \varepsilon)s_4((2m^2 + s_4)(s_4 - t_1) - (2m^2 + s_4 + t_1)u_1)}{(m^2 + s_4)t_1u_1} \right\}. \tag{5.64}
\]

Most of the integrals presented here were already derived in [44] and we agree on the common results. Note however that we have extended almost all integrals to \( O(\varepsilon) \). We need \( O(\varepsilon) \) when the integrals also have a soft divergence, i.e., when they are \( \sim 1/s_4^2 \), which will result in an extra \( 1/\varepsilon \), see next section. Of course those \( O(\varepsilon) \) parts needed in our processes were already presented in [44], but our extended results may become useful for other processes.

### 5.4 Phase-Space Slicing

Now that we have completed the necessary angular integrations and identified the collinear singularities, let us briefly return to the infrared singularities. Remember that (5.9) allows us to isolate the infrared singularities by introducing a cut \( \Delta \) on an integration diverging for \( s_4 \rightarrow 0 \). Take the \( s_4 \)-integration of a function \( \mathcal{H}(s_4) \) with a soft pole \( s_4^{-1+\varepsilon} S(s_4) \) and a finite \( \mathcal{F}(s_4) \) part, i.e., both \( S \) and \( \mathcal{F} \) are well behaved for \( s_4 \rightarrow 0 \) when \( \varepsilon = 0 \) and \( S(0) \neq 0 \). Then

\[
\int_{0}^{s_4_{\text{max}}} ds_4 \mathcal{H}(s_4) \equiv \int_{0}^{s_4_{\text{max}}} ds_4 \left[ s_4^{-1+\varepsilon} S(s_4) + \mathcal{F}(s_4) \right]
\]
\[
\begin{align*}
= & \int_0^{s_4} d s_4 \left[ \frac{\Delta}{\varepsilon} \delta(s_4) S(s_4) + \{ S(s_4) - S(0) \} s_4^{-1+\varepsilon} + F(s_4) \right] + \int_{s_4}^{s_4^{\text{max}}} d s_4 H(s_4) \\
\simeq & \int_0^{s_4^{\text{max}}} d s_4 \left[ \frac{\Delta}{\varepsilon} \delta(s_4) S(s_4) + \Theta(s_4 - \Delta) H(s_4) \right] \\
\end{align*}
\]  

(5.65)

In the last step we have assumed that \( \Delta \) is chosen small enough to be negligible with respect to the 2 \( \to \) 2 Mandelstam variables (5.12) and \( m^2 \). Then \( S(s_4) - S(0) \simeq 0 \) in the range \( 0 \leq s_4 \leq \Delta \) and the integral of \( F(s_4) \) from 0 to \( \Delta \) gives approximately zero as well. In practice one has to choose \( \Delta \) so small that the integral over \( s_4 \) does not change anymore, \( \Delta = 10^{-5} \ldots 10^{-7} m^2 \) guarantees that the approximation is valid for our cross sections.

As we can see the integral has been split into two parts. The part with the soft pole \( S(s_4) \) is now evaluated in 2 \( \to \) 2 kinematics due to the \( \delta(s_4) \). This means that it can be considerably simplified! How can we extract this part from the total result \( H(s_4) \)? If we remember that the \( s_4 \to 0 \) dependence of \( G_c \) in (5.20) is \( s_4^{1+\varepsilon} \) and the only infrared poles come from \( s_4^{-1+\varepsilon} \) terms as shown above, then we can just take the \( \sim 1/s_4^2 \) parts of the matrix elements. By rewriting the results with the underlined variables of (5.23), we make the hidden \( s_4 \)-poles due to \( s_3 = s_4 s_5 \), \( s' = s_4 s' \) and \( s'' = s_4 s'' \) appear explicitly. Then we can directly collect all contributing terms and drop the rest. We can also use the \( s_4 \to 0 \) limit of (5.24) to simplify the algebraic structure further: \( u_5 \to -s \), \( u_6 \to u_1 \) and \( u_7 \to t_1 \). Thus it is easy to extract and simplify the part \( \delta(s_4) S(s_4) \) in (5.65). It will be given in terms of the 2 \( \to \) 2 Mandelstam variables \( s \), \( t_1 \) and \( u_1 \) and the reduced 2 \( \to \) 3 Mandelstam variables \( s_3 \), \( s' \) and \( s'' \).

Let us examine what we get including the \( G_c \) factor. Say we have collected all pole terms in \( s_4^{-2} S(s_4) \), then

\[
G_c s_4^{-2} S(s_4) = \frac{\mu^{1-\varepsilon}}{2\pi (4\pi)^{2+\varepsilon}} \frac{\Gamma (1+\frac{\varepsilon}{2})}{\Gamma (1+\varepsilon)} s_4^{-1+\varepsilon} S(s_4) \\
= \frac{\mu^{1-\varepsilon}}{2\pi (4\pi)^{2+\varepsilon}} \frac{\Gamma (1+\frac{\varepsilon}{2})}{\Gamma (1+\varepsilon)} \frac{s_4^{-1+\varepsilon}}{m^{1+\varepsilon}} \Delta^\varepsilon \varepsilon S(0) \\
= C_c \left( 1 - \frac{3}{8} \zeta(2) \varepsilon^2 \right) \left( \frac{\Delta}{m} \right)^\varepsilon \frac{1}{\varepsilon} \frac{S(0)}{2\pi^2} + \mathcal{O}(\varepsilon^3) \ .
\]

(5.66)

Note that we can rewrite \( G_c \), which parametrizes the difference of the 2 \( \to \) 3 and 2 \( \to \) 2 phase-spaces, see (5.19), using the integration factor \( C_c \) that occurs in all the virtual loop integrals, see (3.5) and (3.6). This is of course expected, since the soft limit has effectively 2 \( \to \) 2 kinematics and its infrared poles cancel those of the virtual contributions. The \( 1/\varepsilon \) infrared pole is clearly exhibited in (5.66) and can in combination with a potential collinear pole in \( S(0) \) give rise to \( 1/\varepsilon^2 \) poles.

It is easy to calculate \( S(0) \) algebraically and thus the cancellation of the infrared poles can be performed explicitly. The remaining “hard” real piece is infrared safe due to the \( \Delta \) cutoff. This method which singles out the part of the phase-space which is
5.4. Phase-Space Slicing

...
Chapter 6

Mass Factorization

Using the work of the last three chapters, we find that the infrared singularities cancel in the sum of virtual and real contributions, as guaranteed by the Bloch-Nordsieck and Kinoshita-Lee-Nauenberg theorems [70], respectively. This includes collinear (mass) singularities, if they are accompanied by an infrared singularity, i.e., \( 1/\varepsilon^2 = 1/\varepsilon_R \cdot 1/\varepsilon_M \) terms. However, there still can be singularities \( 1/\varepsilon \) left over, which are purely collinear in nature. We wish to show now how these singularities can be “absorbed” in a redefinition of the parton densities, which are convoluted with the partonic cross sections to obtain the experimentally measurable hadronic cross sections. A complete proof of mass factorization is of course not the aim here. However, it is useful to see in detail how the method works for one particular subprocess, since one can then by analogy easily write down the formulae for all the other kinds of subprocesses occurring here. The proof that this procedure can indeed be generalized and that the redefinition of the parton densities is universal, i.e., the same in all QCD processes, can be found in the literature. An extension of the methods used here is for example employed in [84] for the general proof. Note that we will have to deal with initial collinear singularities only in our subprocesses.

It is fortunate that one of the \( 2 \rightarrow 3 \) subprocesses of our calculation is ideal for the demonstration. In NLO photoproduction one encounters a new type of subprocess with a light (anti)quark in the initial state, for which we will use the external momentum and color assignment

\[
\gamma(k_1) + q_1^*(k_2) \rightarrow Q_k(p_1) + \bar{Q}_k(p_2) + q(k_3). \tag{6.1}
\]

The squared matrix element calculated from the graphs shown in Fig. 6.1 can be decomposed according to whether the photon couples to the heavy quark with charge \( e_Q \) (in units of \( e \)) in the “Bethe-Heitler” graphs (a) and (b), or to the light quark with charge \( e_q \), as for the “Compton” graphs (c) and (d):

\[
|\vec{M}_{\gamma q}|^2 = M_{\gamma q}^* M_{\gamma q} = E_q g_\gamma^4 \varepsilon^2 F^2 \left[ e_Q^2 \tilde{A}_1 + e_q^2 \tilde{A}_2 + e_q e_Q \tilde{A}_3 \right], \tag{6.2}
\]

where \( \tilde{A}_3 \) denotes the contribution of the interference of both types of subprocesses. Notice that since we now have only one boson in the initial state, the photon, only one factor
E\_c appears in (6.2), see the discussion of (2.12). Since this production mechanism occurs for the first time in NLO and there are no gluons in the final state, we do not encounter IR singularities in the calculation. All (single) poles can be solely attributed to collinear configurations, hence our choice of this subprocess to show the treatment of collinear singularities.

The 2 \to 3 phase space integration including the partial fractioning proceeds just as was explained in Chap. 5, and so we can immediately quote the results here

\[
\frac{d^2\tilde{\sigma}^{(1)}_{\gamma q A_3}}{dt_1 du_1} = \frac{C_F}{2} F_c G_c^H E_c e_c^2 \varepsilon e_\gamma^2 \frac{1}{\varepsilon} \Delta A_i^{\text{pole}} + O(1),
\]

\[
\Delta A_i^{\text{pole}} = -\frac{1}{u_1} (2 - x_2) \left( \frac{x_2 t_1}{u_1} + \frac{u_1}{x_2 t_1} \right) \left[ \frac{2m^2(x_{2s})}{(x_{2t_1}u_1)} - 1 \right],
\]

\[
A_i^{\text{pole}} = -\frac{1}{u_1} \left(1 + (1 - x_2)^2\right) \left\{ \frac{x_2 t_1}{u_1} + \frac{u_1}{x_2 t_1} + \frac{4m^2(x_{2s})}{(x_{2t_1}u_1)} \left[ 1 - \frac{m^2(x_{2s})}{(x_{2t_1}u_1)} \right] \right\},
\]

\[
\Delta A_2^{\text{pole}} = -\frac{1}{t_1} (2x_1 - 1) \left[ \frac{t_1^2 + (x_1 u_1)^2}{(x_1 s)^2} - \frac{2m^2}{x_1 s} \right],
\]

\[
A_2^{\text{pole}} = -\frac{1}{t_1} \left[ x_1^2 + (1 - x_1)^2 \right] \left[ \frac{t_1^2 + (x_1 u_1)^2}{(x_1 s)^2} + 2 \frac{m^2}{x_1 s} \right],
\]

where only the (collinear) pole contributions are given and \( e_i^2 \) denotes \( e_Q^2, e_c^2, \) and \( e_Q e_a \) for \( i = 1, 2, \) and \( 3, \) respectively. The interference contribution \( \tilde{A}_3 \) is not shown, because it is completely finite. \( \tilde{A}_3 \) together with the other finite parts is available upon request.
the lengthy expressions will not be given here. Two new variables have been introduced:

\[ x_1 \equiv -\frac{t_1}{s + u_1} \quad \text{and} \quad x_2 \equiv -\frac{u_1}{s + t_1}. \quad (6.4) \]

Note that we have not minimized the occurrence of these new variables in (6.3) to keep the combination of these variables with \( s, t_1, \) and \( u_1 \) in the results obvious. As no double poles can exist due to the absence of IR singularities, one needs \( G_e \) in (5.19) only to \( \mathcal{O}(\varepsilon) \) when writing down the partonic cross section (6.3):

\[ G_{\varepsilon}^H \equiv \frac{2(4\pi)^4(s_4 + m^2)}{s_4} G_e = 16\pi \left[ 1 + \frac{\varepsilon}{2} \left( \gamma_E - \ln(4\pi) + \ln \frac{s_4^2}{\mu^2(s_4 + m^2)} \right) \right] + \mathcal{O}(\varepsilon^2), \quad (6.5) \]

where we have also absorbed some additional factors into \( G_{\varepsilon}^H \) for convenience.

We see that \( \tilde{A}_1^\text{pole} \) corresponds to the \( \mathcal{O}(1) \) of \( \tilde{B}_\text{QED} \) found in the LO photon-gluon subprocess (2.21), but with the replacement \( (s, t_1, u_1) \to (x_2 s, x_2 t_1, u_1) \). Noting that

\[ \delta[(x_2 s) + (x_2 t_1) + u_1] = \frac{1}{s + t_1} \delta \left( x_2 + \frac{u_1}{s + t_1} \right) = \frac{x_2}{u_1} \delta \left( x_2 + \frac{u_1}{s + t_1} \right), \quad (6.6) \]

we find that the \( \delta \)-function of the \( 2 \to 2 \) phase space (2.24) sets \( x_2 \) to just the right value (6.4) with the same replacement. Thus collecting all the factors, we find that we can write the \( \tilde{A}_1^\text{pole} \)-part of (6.3) in the following form

\[ \frac{\alpha_s}{2\pi} \int_0^1 dx_2 \tilde{P}_{gg}(x_2) \left[ \frac{2}{\varepsilon} + \tilde{E}_{gg}(\mu^2) \right] x_2 \left[ \frac{d^2 \sigma_{gg}^{(0)}}{dt_1 du_1} \right] \left( s \to x_2 s \right). \quad (6.7) \]

Here \( \tilde{E}_{gg} \) collects finite terms and depends not only on the usual kinematic variables, but also on the mass scale \( \mu \) introduced to keep the coupling dimensionless. The functions \( \tilde{P}_{gg} \) can be directly read off

\[ P_{gg}(x) = P_{gg}(x) = C_F \left[ \frac{1 + (1 - x)^2}{x} \right], \quad \Delta P_{gg}(x) = \Delta P_{gg}(x) = C_F(2 - x). \quad (6.8) \]

We find that this is exactly the LO (anti)quark to gluon splitting function of [85]!

This splitting function corresponds to the probability that a quark with momentum \( k \) sends out a collinear gluon with momentum \( xk \) and thus moves on with momentum \((1 - x)k\). In our \( \tilde{A}_1^\text{pole} \) case we then obviously must have the momentum of the exchanged gluon in Fig. 6.1 (a) and (b) set to \( x_2 k_2 \), i.e., the gluon is emitted collinearly to the light quark with a fraction \( x_2 \) of its momentum. This explains the appearance of the splitting function depending on \( x_2 \). The outgoing light quark has then the momentum \( k_3 = (1 - x_2)k_2 \). The propagator of the gluon is found to be \( \sim 1/l' = 1/(x_2 k_2)^2 \) = \text{“}1/0\text{”} \), which is readily identified as the source of the collinear poles, see (5.10). Finally, the exchanged
gluon with momentum $x_2 k_2$ couples to the heavy quark line. But then this upper part of the diagram is just like the Born amplitude for $\gamma g \rightarrow Q\bar{Q}$ with the replacement $k_2 \rightarrow x_2 k_2$. So the appearance of the LO cross section with $(s, t_1, u_1) \rightarrow (x_2 s, x_2 t_1, u_1)$ is a natural consequence of the incoming light-like momentum $x_2 k_2$, e.g., $t_1 = -2 k_2 \cdot p_2 \rightarrow -2 x_2 k_2 \cdot p_2 = x_2 t_1$, and $x_2$ is fixed by (6.6). Our results so far are depicted by Fig. 6.2 (a) and (b).

![Factorized Feynman diagrams](image)

**Figure 6.2:** Factorized Feynman diagrams for obtaining the collinear contributions of Fig. 6.1. There is no factorized diagram corresponding to Fig. 6.1 (c).

Why did no similar collinear singularity occur for setting the heavy quark propagator on-shell in Fig. 6.1 (a) and (b)? The heavy quark propagator momentum in Fig. 6.1 (a) is $k_1 - p_1$. So let us assume for the three-momentum collinear emission $k_1 - \vec{p}_1 = x \vec{k}_1$ with $x \geq 0$. Then the denominator of the propagator becomes

$$u_7 = -(2 k_1 \cdot p_1 - 2 \left| \vec{k}_1 \right| \sqrt{(1 - x)^2 k_1^2 + m^2 - (1 - x)k_1^2}}. \quad (6.9)$$

We see, that this can only become zero for $m = 0$ and $x \leq 1$. Then for $m = 0$ we recover four-momentum collinearity $k_1 - p_1 = x k_1$ with $0 \leq x \leq 1$. Note that there is no soft limit $k_1 \rightarrow 0$ possible here to set the propagator on-shell, since the center-of-mass energy $s = 2k_1 \cdot k_2 \geq 4m^2$. The next possibility, with a propagating gluon decaying to a heavy quark and antiquark pair, is realized in Fig. 6.1 (c) and (d) and can be treated similarly: The propagator momentum is $p_1 + p_2$, so we assume a collinear decay $\vec{p}_1 = x(\vec{p}_1 + \vec{p}_2)$ with $x \geq 0$. So this time the denominator of the propagator is

$$s_5 = (p_1 + p_2)^2 = 2m^2 + 2 \sqrt{p_1^2 + m^2} \sqrt{\left( \frac{1 - x}{x} \right)^2 p_1^2 + m^2 - \frac{1 - x}{x} p_1^2}, \quad (6.10)$$

which again can only become zero for $m = 0$ and $x \leq 1$. We once more find for $m = 0$ the four-momentum collinearity $p_1 = x(p_1 + p_2)$ with $0 \leq x \leq 1$ and that no soft limit is

---

1. $x \geq 0$ is necessary for energy conservation.
2. The special case $x = 0$ leads to the same conclusion, we assume $x \neq 0$ in the following.
possible. The final possibility in QCD involving massive particles, emitting an external gluon from a heavy quark line $Q \rightarrow Qg$, will become relevant for $\gamma g \rightarrow Q\bar{Q}g$ and can be analyzed in exactly the same fashion as $g \rightarrow Q\bar{Q}$ with almost the same result. The only difference is that now for soft collinear emission ($k_3 = 0$), we can obtain an on-shell propagator in spite of the masses. However, these soft plus collinear singularities cancel against virtual contributions and thus do not have to be factorized. So we find that for non-zero mass propagators, we do not have any (surviving) collinear singularities. Hence we could have regularized the collinear singularities by giving the massless particles a small mass $\lambda$. Then the expressions would have diverged for $\lambda \rightarrow 0$. This explains the alternative name “mass singularities” and the label “mass (singularity) factorization”.

Turning now to the “Compton” graphs of Fig. 6.1 (c) and (d), we see that (c) can not have a collinear part, since the light quark propagator is attached to two incoming particles. If it became on-shell, then indeed the center-of-mass energy would be zero, so this is kinematically forbidden. We do not have to worry about the gluon propagator either, since it is attached to heavy particles. On the other hand in Fig. 6.1 (d) the light quark propagator is attached only to one incoming particle, the photon, and thus we expect the collinear case depicted in Fig. 6.2 (d). So the antiquark propagator now has momentum $x_1 k_1$ and correspondingly we find for the outgoing light quark $k_3 = (1 - x_1) k_1$. The collinear propagator diverges $\sim 1/\mu' = (xk_1)^2 = 1/0$ and the attached LO subprocess is the quark-antiquark annihilation$^3$ (2.29) with the replacement $(s, t_1, u_1) \rightarrow (x_1 s, t_1, x_1 u_1)$ due to the incoming antiquark momentum $x_1 k_1$. So we expect for the $A_2^\text{pole}$-part

$$\frac{\alpha_s}{2\pi} \int_0^1 dx_1 \tilde{P}_{q\bar{q}}(x_1) \left[ \frac{2}{\varepsilon} + \tilde{E}_{q\bar{q}}(\mu^2) \right] x_1 \frac{d^2 \tilde{\sigma}_{q\bar{q}}^{(0)}}{dx_1 dx_1} \left( s \rightarrow x_1 s \right) , \quad (6.11)$$

which is readily confirmed by comparing with (6.3). We can also read off the photon-(anti)quark splitting functions

$$P_{q\bar{q}} = P_{q\gamma} = e_q^2 N_C \left[ x^2 + (1 - x)^2 \right] , \quad \Delta P_{q\bar{q}} = \Delta P_{q\gamma} = e_q^2 N_C (2x - 1) , \quad (6.12)$$

and they indeed have exactly the form derivable from [85].

At this point we should try to give more physical meaning to our results. We have found that the singularities occur when the propagator of an internal (massless) particle goes on-shell. But the propagator basically corresponds to the time the virtual particle can propagate according to the uncertainty principle$^4$. So as the propagator denominator goes to zero, the propagation time becomes infinite. In other words, the internal particle then becomes (quasi-)real and can be treated on the same footing as external particles. This can occur whenever an internal momentum happens to become parallel to the momentum of an

---

$^3$The momenta are reassigned $\tilde{q}(k_1) + \bar{q}(k_2) \rightarrow Q(p_1) + \bar{Q}(p_2)$, which leaves (2.29) unchanged.

$^4$This is most evident in non-relativistic perturbation theory, where the “propagator” is simply the inverse of the energy difference between the virtual and real state and $\Delta t \sim 1/\Delta E$. That the relativistic propagator is the corresponding generalization is easily shown, see for example [86].
external (massless) particle. But that this happens by chance for two unrelated (internal and external, respectively) particles, both obeying their local momentum constraints, is unlikely and hence suppressed by phase space. The only probable subprocesses leading to a contribution will be those, in which either an incoming particle decays collinearly to an internal particle or an internal particle decays collinearly into an external particle. We will only consider the first case in the following, because it is relevant for our calculation, but the second case can be analyzed analogously. Obviously this reaction happens in two steps with very different associated time scales. First one has the collinear decay into a quasi-real particle followed by a long ("infinite") propagation of the produced particle. Then on a very short time scale (large propagator virtuality) a hard scattering subprocess occurs. It is obvious that we can describe this by the probability of the external particle decaying into the (quasi-)real particle (the splitting function) times the cross-section of the hard scattering with the (quasi-)real particle (for NLO cross sections this will be a LO cross section, as one interaction is used up for the collinear splitting) times the regularized infinity of the on-shell propagator and then integrated over the possible collinear momenta. This is exactly the form of our results encountered in (6.7) and (6.11).

We can now draw some additional conclusions: Firstly, we immediately understand why the interference of Fig. 6.1 (a) and (b) with (c) and (d) gives \( \hat{A}_1^\text{pole} = 0 \). The LO amplitudes left over after separating off the long time scale subprocess (splitting and propagating) belong to different subprocesses and hence cannot interfere. Secondly, it is clear that we need to add Fig. 6.2 (a) and (b) amplitudes coherently to obtain \( \hat{A}_1^\text{pole} \), since both short time scale LO amplitudes are needed, see Fig. 2.2. Thirdly, we can simply square Fig. 6.2 (d) on its own to obtain \( \hat{A}_2^\text{pole} \), since Fig. 6.1 (c) cannot have the same long time scale subprocess and indeed one short time scale LO amplitude is enough, see Fig. 2.4. However, the last statement concerns contributions within a gauge invariant part, and is strictly only true when we use a physical gauge, for example an axial one\(^5\). When using our polarization sum (2.15), one obtains singularities from the interference of Fig. 6.1 (c) with (d). But the final (gauge invariant) result (6.11) has of course the structure we expect from the third argument. However, the first two conclusions are directly valid in any gauge, since they concern gauge invariant parts. The final step leading to the mass factorization procedure now becomes conceptionally simple: as the on-shell propagating internal particles are (quasi-)real, we should be able to pass them off as "partons". We can then try to absorb the singularities in a redefinition of the "bare" parton distributions used in calculating hadronic cross sections. Since these distributions parametrize our ignorance about processes at large time scales and distances anyway, we can safely declare these redefined densities as the "measurable" ones. Of course as mentioned above, we skip here the all important but difficult proof, that this redefinition is universal, e.g., the same in all (factorizable) QCD processes, see for example [84]. The final procedure is remarkably similar to the redefinition of the "bare" fields and couplings

\(^5\)One then finds, that the divergence of the interference term between Fig. 6.1 (c) and (d) is \( \sim \eta \delta \left( k_3 - u_1 \right) k_3^2 \left[ u_1 k_1^2 \left( \eta \cdot k_1 \right) \right] \), i.e., vanishes identically in the collinear limit \( k_3 = \left( 1 - x_1 \right) k_1 \). Of course in the end all terms proportional to \( \eta \delta \), which fixes the gluon field \( A^\mu \) via \( \eta \cdot A = 0 \), vanish.
in the renormalization procedure. But here we will be forced to leave the purely partonic level in order to obtain the final finite results. This reflects the fact that partons are not directly observable.

First let us define a finite reduced cross section \( d\tilde{\sigma}_{\gamma q}^{(1)} \) by

\[
\frac{d^2\tilde{\sigma}_{\gamma q}^{(1)}}{dt_1 du_1}(\mu_f^2) = \frac{d^2\tilde{\sigma}_{N\gamma q}^{(1)}}{dt_1 du_1}(\mu_f^2, \mu^2),
\]

(6.13)

\[
\frac{d^2\tilde{\sigma}_{N\gamma q}^{(1)}}{dt_1 du_1}(\mu_f^2, \mu^2) = \int_0^1 dx_1 x_1 G_{q}(x_1, \mu_f^2, \mu^2) \left[ \frac{d^2\tilde{\sigma}_{\gamma g}^{(0)}}{dt_1 du_1}(u_1 \to x_1 u_1) \right] + \int_0^1 dx_2 x_2 G_{g}(x_2, \mu_f^2, \mu^2) \left[ \frac{d^2\tilde{\sigma}_{\gamma g}^{(0)}}{dt_1 du_1}(s \to x_2 s) \right] (6.14)
\]

\[
G_{ij}(x_k, \mu_f^2, \mu^2) = \frac{\alpha_s(\mu^2)}{2\pi} \left[ \frac{\tilde{P}_{ij}(x_k) \gamma_E}{\varepsilon} + \tilde{F}_{ij}(x_k, \mu_f^2, \mu^2) \right].
\]

(6.15)

Comparing this to (6.7) and (6.11), we see that \( d\tilde{\sigma}_{\gamma q}^{(1)} \) becomes finite as long as the \( \tilde{F}_{ij} \) are finite. What we use for the \( \tilde{F}_{ij} \) is then another choice of scheme, which is in principle independent of our choice in the renormalization procedure. Also the factorization scale should in principle be independent of the regularization scale \( \mu \), which we had set equal to the renormalization scale \( \mu_r \). We see that due to the \( G_i^H \) of (6.5) this scale is introduced in a logarithm proportional to the splitting function in the finite \( \tilde{E}_{ij}(\mu^2) \) of (6.7) and (6.11). To eliminate this logarithmic dependence on the regularization scale explicitly in the reduced cross section, we will subtract \( \ln(\mu_f^2/\mu^2) \) proportional to the splitting function in the \( \tilde{F}_{ij} \) of (6.15). Then the reduced cross section will only depend on the new factorization scale \( \mu_f \). Furthermore a glance at (6.5) suggests, that the pole again comes with the usual finite artifacts of dimensional regularization. So we will use the \( \overline{\text{MS}} \) prescription and additionally only eliminate these artifacts. The general \( \overline{\text{MS}} \) factorization choice then amounts to

\[
\tilde{F}_{ij}(x, \mu_f^2, \mu^2) = \tilde{P}_{ij}(x) \left( \gamma_E - \ln(4\pi) + \ln \frac{\mu_f^2}{\mu^2} \right),
\]

(6.16)

and we will use it throughout our calculation. Finally there is a hidden choice of finite terms implied in (6.14). To what order in \( \varepsilon \) are we going to use the LO cross sections? Our choice is to use them to \( O(\varepsilon) \), not \( O(1) \), which leads to finite terms in conjunction with the \( 1/\varepsilon \) pole. This is consistent with the conventional definition of \( \overline{\text{MS}} \) factorization, which uses \( n \)-dimensional cross sections! If we considered our processes at next-to-NLO (NNLO) using \( \overline{\text{MS}} \) factorization, then \( O(\varepsilon^2) \) parts of the \( n \)-dimensional LO cross sections would have to be included, since they yield finite contributions with the double collinear emission \( 1/\varepsilon^2 \) poles. In principle one could choose to never subtract this type of finite terms by adjusting the order in \( \varepsilon \) appropriately, but in our case the conventional \( \overline{\text{MS}} \) choice is mandatory! As has been mentioned in the discussion of (2.30), helicity conservation is
broken by the commuting \([\gamma_5, \gamma_\mu] = 0\) of the HVBM scheme [54] in the non-physical \(n-4 = \varepsilon\) dimensions. The effect is thus naturally of \(\mathcal{O}(\varepsilon)\) and can contribute only when the LO cross section is multiplied by a pole \(1/\varepsilon\). But such finite terms will be generated from the collinear pole contributions in (6.11). In order to restore helicity conservation, we have to subtract them via (6.14) again, which is simply possible by inserting the LO cross sections to \(\mathcal{O}(\varepsilon)\).

In order to finally factorize the singularities, we use the result, that to all orders in \(\alpha_s\) and lowest order in \(\alpha\), we can write the collinear-singular parton cross section as

\[
d\tilde{\sigma}_{ij}(\mu^2, k_1, k_2) = \sum_{l,m} \int_0^1 dz_1 \int_0^1 dz_2 \Gamma_{il}(z_1, \mu_j^2, \mu^2) \Gamma_{mj}(z_2, \mu_j^2, \mu^2) d\tilde{\sigma}_{lm}(\mu_j^2, z_1 k_1, z_2 k_2),
\]

(6.17)

with \(i, j, l, m = g, q, \bar{q}, \gamma\) and to first order in \(\alpha_s\) we have

\[
\Gamma_{ij}(z, \mu_j^2, \mu^2) = \delta_{ij} \delta(1 - z) + G_{ij}(z, \mu_j^2, \mu^2).
\]

(6.18)

In writing the dependence on the scales \(\mu\) and \(\mu_f\) in (6.17) and (6.18), we refer here only to the additional \(\ln(\mu_f^2/\mu^2)\), see (6.16). We continue using \(\alpha_s(\mu^2)\) and \(F_\varepsilon(\mu^2)\), see (2.25), throughout, and this dependence on \(\mu\) is always implied. It is a simple exercise to convince ourselves that (6.17) together with (6.18) reproduces exactly our result (6.14), when we drop all higher order terms and those suppressed by \(\alpha/\alpha_s\). The only remaining structures are then \(\Gamma_{gg}\Gamma_{qg}d\tilde{\sigma}_{qg}, \Gamma_{\bar{q}g}\Gamma_{qg}d\tilde{\sigma}_{qg}\) and \(\Gamma_{gg}\Gamma_{gq}d\tilde{\sigma}_{gq}\), and in \(\mathcal{O}(\alpha_s)\) only the \(G_{ij}\) terms found in (6.14) appear. Note that the extra \(x_1\) and \(x_2\) cancel against \(\frac{d}{d(x_1 x_2)} = \frac{1}{x_1} \frac{d}{d x_1}\) and \(\frac{d}{d(x_2 x_3)} = \frac{1}{x_2} \frac{d}{d x_1}\), respectively. The general factorization prediction for a hadronic cross section with two initial hadrons \(a\) and \(b\) can be written as

\[
d\tilde{\sigma}^{ab}(K_1, K_2) = \sum_{i,j} \int_0^1 dy_1 \int_0^1 dy_2 \tilde{f}^a_i(y_1, \mu^2) \tilde{f}^b_j(y_2, \mu^2) d\tilde{\sigma}_{ij}(\mu^2, y_1 K_1, y_2 K_2),
\]

(6.19)

where \(\tilde{f}^a_i(y, \mu^2)\) denotes the “bare” density of partons of type \(i\) in hadron \(a\) with longitudinal momentum fraction \(y\). Their dependence on the regularization scale \(\mu\) is dictated by the fact\(^6\), that the all orders physical cross section \(d\tilde{\sigma}^{ab}\) cannot depend on an arbitrary scale. \(K_1\) and \(K_2\) are the external hadronic momenta of the hadrons \(a\) and \(b\), respectively.

If we now define “dressed” parton densities

\[
\tilde{f}^a_i(x_1, \mu_j^2) = \sum_{i} \int_0^1 dy_1 \int_0^1 dz_1 \delta(x_1 - y_1 z_1) \tilde{f}^a_i(y_1, \mu^2) \Gamma_{ii}(z_1, \mu_j^2, \mu^2),
\]

\[
\tilde{f}^b_j(x_2, \mu_j^2) = \sum_{j} \int_0^1 dy_2 \int_0^1 dz_2 \delta(x_2 - y_2 z_2) \tilde{f}^b_j(y_2, \mu^2) \Gamma_{mj}(z_2, \mu_j^2, \mu^2),
\]

(6.20)

\(^6\)The regularization dependence is often not shown and depends on the regularization method used.
we can rearrange the sums and integrations that occur after inserting (6.17) in (6.19) to an outer sum in $l$ and $m$ over the “dressed” parton densities, where outer integrations over $x_1$ and $x_2$ with the appropriate $\delta$-functions have been added. So our final result has a form very similar to (6.19)

$$d\hat{\sigma}^{ab}(K_1, K_2) = \sum_{l,m} \int_0^1 dx_1 \int_0^1 dx_2 \int_0^1 d\bar{x}_2 \hat{f}_l(x_1, \mu_f^2) \hat{f}_m(x_2, \mu_f^2) d\hat{\sigma}_{lm}(\mu_f^2, x_1 K_1, x_2 K_2),$$

(6.21)

where we now however have a sum over the finite reduced $d\hat{\sigma}_{lm}$! The singularities have disappeared in our definition of “dressed” partons (6.20). Since the physical cross section $d\hat{\sigma}^{ab}$ and the reduced cross sections are finite, we now assume the dressed partons to be finite by construction. Thus (6.21) finally allows us to obtain physical predictions after we have computed the relevant (reduced) cross sections, like in (6.13). Note that in other subprocesses there are LO contributions, i.e., generally one has $d\hat{\sigma} = d\hat{\sigma}^{(0)} + d\hat{\sigma}^{(1)}$. We see from (6.17) and (6.18), that we can generally extract the needed reduced cross sections to $O(\alpha_s)$ from

$$d\hat{\sigma}^{(0)}_{ij} = d\hat{\sigma}_{ij}^{(0)},$$

$$d\hat{\sigma}^{(1)}_{ij}(\mu_f^2) = d\hat{\sigma}_{ij}^{(1)}(\mu_f^2) - d\hat{\sigma}^{(1)}_{Mij}(\mu_f^2, \mu^2),$$

$$d\hat{\sigma}^{(1)}_{Mij} = \sum_{l,m} \int_0^1 d\bar{x}_1 \int_0^1 d\bar{x}_2 \Gamma_{ij}(\bar{x}_1, \mu_f^2, \mu^2) G_{ij}(\bar{x}_2, \mu_f^2, \mu^2) d\hat{\sigma}_{lm}^{(0)}(\bar{x}_1 k_1, \bar{x}_2 k_2).$$

(6.22)

The dependence of the “dressed” partons (6.20) on only the factorization scale $\mu_f$ is again motivated by the fact, that the physical cross section in (6.21) is independent of the arbitrary scale $\mu_I$. Technically, the “dressed” partons in (6.20) depend on the scale $\mu_f$ through the logarithm in the $\Gamma_{ij}$ functions according to (6.18), (6.15) and (6.16). Thus we can by simple differentiation obtain the LO RGE of the form

$$\frac{d f_i(x, \mu_f^2)}{d \ln(\mu_f^2)} = \frac{\alpha_s(\mu_f^2)}{2\pi} \sum_j \int_x^1 \frac{dy}{y} f_j(y, \mu^2) P_{ij} \left( \frac{x}{y} \right)$$

$$O(\alpha_s) \frac{\alpha_s(\mu_f^2)}{2\pi} \sum_j \int_x^1 \frac{dy}{y} f_j(y, \mu_f^2) P_{ij} \left( \frac{x}{y} \right).$$

(6.23)

In the second line of (6.23), we have assumed that $\mu_f$ is of the order $\mu$, which means that both $\alpha_s(\mu_f^2)$ and $\alpha_s(\mu^2)$ are sufficiently small to serve as expansion parameter. Also then the logarithm of the ratio of these two scales cannot become large and spoil the expansion. So we can employ $\alpha_s(\mu^2) \simeq \alpha_s(\mu_f^2) + O[\alpha_s^2(\mu_f^2), \alpha_s^2(\mu_f^2) \ln(\mu^2/\mu_f^2)]$, compare (4.31), and $\tilde{f}_i(x, \mu_f^2) = \tilde{f}_i(x, \mu_f^2) + O[\alpha_s(\mu_f^2), \alpha_s(\mu_f^2) \ln(\mu_f^2/\mu_f^2)]$, see (6.20) and (6.18). But we have also changed the nature of the differential equation by writing the second line! This is however justified upon closer physical examination: We can now construct parton distributions at a low scale $\mu_f$ where we first trust factorization to be valid. So this is our
Chapter 6. Mass Factorization

initial scale, setting a lower limit for “hard” scales whose occurrence allows to separate off a “hard” subprocess calculable with perturbative methods. Then we use (6.23) to “evolve” these partons to a higher scale7 \( \mu_f \sim \mu \sim m \) close to the typical hard scale \( m \) of the process, so that the reduced cross sections do not contain large logarithms of the type \( \ln(\mu_f/m) \). We see that we are summing logarithms along the way from \( \mu_{f0} \) to \( \mu_f \), when iteratively solving (6.23). Indeed it can be shown, that our mathematical sin of writing the second line in (6.23) corresponds to the physical good work of resumming the leading logarithmic (LL) corrections to all orders. These appear in axial gauges as strongly ordered ladder graphs \( \mu_{f0}^2 \ll k_{1T}^2 \ll \ldots \ll k_{nT}^2 \ll \mu_f^2 \), with the \( k_T \) being the transverse momenta along the rungs of the ladders. Summation over all ladders will lead to (6.23). A detailed derivation can be found in [87], see also [88]. In the first line of (6.23), we have basically derived the result for only one rung. We can now use the LO RGE for determining the scale dependence of the parton distributions to LL accuracy. A corresponding NLO RGE, which additionally resums logarithms accompanied by an extra power of \( \alpha_s \), next-to-leading logarithms (NLL), can be obtained similarly.

Since however the partons in (6.21) are convoluted with both the LO and NLO (reduced) cross sections, one should use the \( \mathcal{O}(\alpha_s^2) \) NLO RGE [26, 27, 89] and thus the summation of NLL. To see this, we will write down the solution of (6.23) for LO and NLO in the hypothetical case8 when there is only one parton \( f \) and one \( f \to f \) splitting function \( P \). The LO and NLO cases correspond to inserting \( P = P^{(0)} + \mathcal{O}(\alpha_s) \) and \( P = P^{(0)} + \frac{\alpha_s}{2\pi} P^{(1)} + \mathcal{O}(\alpha_s^2) \) in (6.23), respectively. The appropriate LO and NLO “running” of \( \alpha_s \) also has to be used, see (4.30) and (4.34), respectively. We exploit the fact that for Mellin moments \( a_n \equiv \int_0^1 dx x^{n-1} a(x) \) the convolution becomes a simple product

\[
\left[ \int_0^1 \frac{dx}{y} a(y) b\left(\frac{x}{y}\right) \right]_n = a_n b_n.
\]

Then we get from (6.23) the simple NLO differential equation and its solution in Mellin momentum space

\[
\frac{df_n(\mu_f^2)}{d\alpha_s(\mu_f^2)} = -\frac{2}{\beta_0 \alpha_s(\mu_f^2)} f_n(\mu_f^2) \left\{ P_n^{(0)} + \frac{\alpha_s(\mu_f^2)}{2\pi} \left( P_n^{(1)} - \frac{\beta_1}{2\beta_0} P_n^{(0)} \right) + \mathcal{O}(\alpha_s^2(\mu_f^2)) \right\}, \quad (6.24)
\]

\[
f_n(\mu_f^2) = f_n(\mu_{f0}^2) \left[ \frac{\alpha_s(\mu_f^2)}{\alpha_s(\mu_{f0}^2)} \right]^{-\frac{2}{\beta_0} P_n^{(0)}} \cdot \left\{ 1 - \frac{\alpha_s(\mu_f^2) - \alpha_s(\mu_{f0}^2)}{\beta_0} \left( P_n^{(1)} - \frac{\beta_1}{2\beta_0} P_n^{(0)} \right) + \mathcal{O}(\alpha_s^2(\mu_f^2, \mu_{f0}^2)) \right\}, \quad (6.25)
\]

and the LO differential equation and solution correspond to taking \( \mathcal{O}(1) \) in the curved brackets. We see that \( f_n^{\text{NLO}} - f_n^{\text{LO}} \sim \alpha_s \). The inversion of the Mellin transformation9 \( a(x) = \frac{1}{2\pi i} \int_C d\mu x^{\mu-1} a_n \) applied to \( f_n(\mu_f^2) \), keeps this \( \alpha_s \)-structure intact. Thus a LO cross

7To not confuse names, one can think of (6.23) written with \( \mu' \) instead of \( \mu_f \) as “evolution” variable. We then “evolve” from \( \mu_{f0} \) to \( \mu_f \).

8This is in practice realized for the evolution of flavor non-singlet combinations of quark distributions.

9The simplest integration contour \( C \) runs from \( c-i\infty \) to \( c+i\infty \) with real \( c \), which lies to one side of all singularities of \( a_n \) in the complex \( n \)-plane, see for example [90].
sections times the $\alpha_s$ part of the NLO partons has the same order as a NLO reduced cross section times the $O(1)$ LO partons, and the error of multiplying a NLO reduced cross sections with the $\alpha_s$ part of the NLO partons is NNLO. So we have to use the NLO RGE evolved partons in our NLO calculations (and the LO ones for LO calculations) to achieve consistent orders of $\alpha_s$. A final point is that collinear singularities occur only for massless particles, so we should stay consistent with our renormalization choice and always evolve only the $n_f$ light flavors as partons and not the heavy one.

It is important to realize that (6.20) mixes different contributions. In particular in our example we have to introduce the bare parton distribution $f^a_j(y_1, \mu^2)$, and thus of course also its “dressed” counterpart, to absorb $\Gamma_{\phi^0}(z_i, \mu^2, \mu^2)$. So for a factorization scheme independent result we need to consider “resolved” photons with their own parton content. The photon can act like a hadron, by fluctuating into a virtual state with the appropriate quantum numbers, and thus it should not surprise us to see that this possibility has to be included. Obviously we will then also get resolved contributions to the cross section, in which the physical photon interacts via its partonic content. In the hadronic cross section (6.21), setting $a = \gamma$ denotes a physical photon and $l = \gamma$ an elementary photon. So for the “direct” part of (6.21), we use the (zeroth order in $a$) probability distribution for finding an elementary photon in the physical photon $f^a_i(x_1, \mu^2) = \delta(1 - x_1)$ with the reduced partonic cross sections for photoproduction. On the other hand for the resolved part of (6.21), we use the probability distributions for finding a parton $l = g, q, \bar{q}$ in the physical photon $f^a_i(x_1, \mu^2)$ with the reduced partonic cross sections for hadroproduction. Note that since photonic densities are of $O(\alpha_s/\alpha_s)$, LO resolved contributions effectively have the same order in the coupling constants as LO direct contributions. Similarly, NLO direct and NLO resolved contributions belong together. So we use for photoproduction at $O(\alpha)$

$$d\tilde{\sigma}^{gh}(K_1, K_2) = \sum_m \int_0^1 dx_2 f^m_{\gamma}(x_2, \mu^2) \, d\tilde{\sigma}^{\mu}(\mu^2, K_1, x_2 K_2) ,$$

$$+ \sum_{l,m} \int_0^1 dx_1 \int_0^1 dx_2 \, f^l_\gamma(x_1, \mu^2) \, f^m_\gamma(x_2, \mu^2) \, d\tilde{\sigma}^{lm}(\mu^2, x_1 K_1, x_2 K_2) , \quad (6.26)$$

with $l$ now restricted to $g, q, \bar{q}$. A further complication arises here, because the parton content of longitudinally, i.e., circularly, polarized photons is experimentally completely unknown for the time being, and one has to rely on realistic models [91] when estimating the size of the resolved contribution. However, it has been demonstrated in [33] that even for large spin-dependent photonic densities, the “background” from resolved photon reactions should be very small for all experimentally relevant total or differential cross sections in the \(\overline{\text{MS}}\) scheme. In particular this is the case at fixed target energies, as for COMPASS with $\sqrt{s_{ep}} \approx 10$ GeV.

For the polarized total charm production cross section at collider energies, the resolved contribution can become as large as about $1/3$ of the direct contribution but with opposite sign [33]. When everything is taken into account, the total charm production
spin asymmetry appears to be too small to be measurable [33] at the polarized HERA option [28]. However, it is expected that for bottom production the resolved part is less important: Though the change in the heavy quark charge $e_b^2/e_c^2 = \left(-\frac{1}{3}\right)^2 / \left(\frac{2}{3}\right)^2 = 1/4$ suppresses the direct part, the minimal $x$ at which the photonic densities in the resolved part are evaluated becomes $m_b^2/m_c^2 \approx 9$ times larger. For example at $\sqrt{s_{\gamma p}} = 200$ GeV with $m_b = 4.5$ GeV and $m_c = 1.5$ GeV, we find $x_{\text{min}} = 2.025 \times 10^{-3}$ and $x_{\text{min}} = 2.25 \times 10^{-4}$, respectively, see (8.10) in Chap. 8. This strongly suppresses the resolved part. So for polarized photoproduction in the $\overline{\text{MS}}$ scheme, the resolved part can be neglected in experimentally relevant circumstances (fixed target energies or bottom at collider energies) as a first approximation. It should also be remarked that for NLO photonic parton densities, unpolarized [92] as well as polarized [93] ones, often the so-called DIS, factorization scheme [94] rather than the $\overline{\text{MS}}$ prescription is used, since it provides a better perturbative stability between LO and NLO quark densities. In this case one either has to transform the densities back to the $\overline{\text{MS}}$ scheme [92, 93], before using them in the calculation of the NLO resolved contribution or one has to use the appropriate DIS, expression for $\tilde{F}_{q\gamma}$ in (6.14), see the Appendix of [94].

We will finish this chapter by quickly deriving the other needed mass factorization subtractions leading to the reduced cross sections. From diagram Fig. 6.3 (a) we see that for the photoproduction real emission we have to subtract

$$\frac{d^2\hat{\sigma}_{\gamma p}^{(1)}}{dt_1 du_1} = \int_0^1 dx_2 \, x_2 \, G_{gg}(x_2, \mu_1^2, \mu_2^2) \, \left[ \frac{d^2\hat{\sigma}_{\gamma g}^{(0)}}{dt_1 du_1} \right] \left( s \to x_2 s \right),$$

where $G_{gg}$ defined according to (6.15) and the LO gluon splitting functions are\(^{10}\)

$$P_{gg}(x) = \Theta(1 - x - \delta) 2C_A \left( \frac{1}{1-x} + \frac{1}{x} - 2 + x(1-x) \right) + P_{gg}^\delta(x),$$

$$\Delta P_{gg}(x) = \Theta(1 - x - \delta) 2C_A \left( \frac{1}{1-x} - 2x + 1 \right) + P_{gg}^\delta(x),$$

$$P_{gg}^\delta(x) = \delta(1-x) \left( \frac{\beta_0}{2} + 2CA \ln \delta \right).$$

Since we have regularized all soft singularities in our calculation by a small parameter $\Delta$ as outlined in Sec. 5.4, we have to stick to the same framework here to deal with the soft $x \to 1$ divergence of $P_{gg}$ and cannot simply use the usual “plus-prescription” $1/(1-x)_+$ of [85]. In (6.28) we have thus introduced another small auxiliary quantity $\delta$ [46, 95]. Of course, $\Delta$ introduced above and $\delta$ are not independent. Inserting (6.28) in (6.27) one gets schematically

$$\int_0^1 dx_2 \, [\delta(1-x_2) A + \Theta(1-x_2-\delta_2) B(x_2)] x_2 \delta(x_2(s + t_1) + u_1) C(x_2 s, x_2 t_1, u_1).$$

\(^{10}\)This form is easy to derive from the conventional one with a $+$-distribution, by insuring that $\int_0^1 dx \, P_{gg}(x)$ gives the same total splitting probability upon taking the $\delta \to 0$ limit.
\[
\begin{align*}
&= \delta(s_4)AC(s, t_1, u_1) + \Theta(s_4 - \delta_2) \left[ \frac{1}{u_1} B \left( \frac{-u_1}{s + t_1} \right) C \left( \frac{-u_1 s}{s + t_1}, \frac{-u_1 t_1}{s + t_1}, u_1 \right) \right], \\
&\text{where we define the small parameter } \delta_2 \equiv \Delta/(s + t_1) \text{ to obtain the appropriate cut-off } \\
&\Theta(s_4 - \Delta) \text{ from } \Theta(\frac{m_4^2}{s + t_1} - \delta). \text{ A subtraction with respect to the other incoming leg would yield a similar expression with } x_1, \delta_1 \text{ and } t_1 \leftrightarrow u_1. \text{ Thus the contribution from mass factorization naturally splits into a soft } (x_i > 1 - \delta_i) \text{ and a hard } (x_i < 1 - \delta_i) \text{ part, which can be added to the corresponding cross sections. } \\
&\beta_0 \text{ in (6.28) again includes only the } n_f \text{ light flavors, since we let only these flavors run.}
\end{align*}
\]

![Factorized Feynman diagrams for obtaining the collinear contributions for the remaining photo- and hadroproduction subprocesses.](Image)

Figure 6.3: Factorized Feynman diagrams for obtaining the collinear contributions for the remaining photo- and hadroproduction subprocesses.

The gluon-gluon cross section of hadroproduction obviously has graphs like Fig. 6.3 (a) with the photon replaced by a gluon, but also those with “non-abelian” LO parts, see Fig. 6.3 (b). Thus we simply get here gluon-gluon fusion (GGF) instead of photon-gluon fusion (PGF) as the LO subprocess, see Fig. 2.2 and Fig. 2.3, and of course this time the graphs are symmetric concerning the incoming particles, so we have to subtract

\[
\frac{d^2 \hat{\sigma}^{(1)}_{ggg}(\mu^2, \mu^2)}{dt_1 du_1} = \int_0^1 dx_1 x_1 G_{gg}(x_1, \mu_1^2, \mu_2^2) \left[ \frac{d^2 \hat{\sigma}^{(0)}_{gg}}{dt_1 du_1} \right] \left( \begin{array}{c}
\frac{\hat{s}}{\hat{u}} \rightarrow x_1 \frac{\hat{s}}{\hat{u}} \\
\frac{\hat{u}_1}{\hat{t}_1} \rightarrow x_1 \frac{\hat{u}_1}{\hat{t}_1}
\end{array} \right),
\]

\[
\frac{d^2 \hat{\sigma}^{(1)}_{ggg}(\mu^2, \mu^2)}{dt_1 du_1} = \int_0^1 dx_1 x_1 G_{gg}(x_1, \mu_1^2, \mu_2^2) \left[ \frac{d^2 \hat{\sigma}^{(0)}_{gg}}{dt_1 du_1} \right] \left( \begin{array}{c}
\frac{\hat{s}}{\hat{u}} \rightarrow x_2 \frac{\hat{s}}{\hat{u}} \\
\frac{\hat{t}_1}{\hat{t}_2} \rightarrow x_2 \frac{\hat{t}_1}{\hat{t}_2}
\end{array} \right).
\]

Similarly the addition of diagram Fig. 6.3 (c) will simply replace LO PGF (2.20) by LO GGF (2.27) for the NLO gluon-quark part of hadroproduction, and thus we need to subtract

\[
\frac{d^2 \hat{\sigma}^{(1)}_{Nggq}(\mu^2, \mu^2)}{dt_1 du_1} = \int_0^1 dx_1 x_1 G_{gq}(x_1, \mu_1^2, \mu_2^2) \left[ \frac{d^2 \hat{\sigma}^{(0)}_{gg}}{dt_1 du_1} \right] \left( \begin{array}{c}
\frac{\hat{s}}{\hat{u}} \rightarrow x_1 \frac{\hat{s}}{\hat{u}} \\
\frac{\hat{u}_1}{\hat{t}_1} \rightarrow x_1 \frac{\hat{u}_1}{\hat{t}_1}
\end{array} \right),
\]

\[
\frac{d^2 \hat{\sigma}^{(1)}_{Nggq}(\mu^2, \mu^2)}{dt_1 du_1} = \int_0^1 dx_1 x_1 G_{gq}(x_1, \mu_1^2, \mu_2^2) \left[ \frac{d^2 \hat{\sigma}^{(0)}_{gg}}{dt_1 du_1} \right] \left( \begin{array}{c}
\frac{\hat{s}}{\hat{u}} \rightarrow x_2 \frac{\hat{s}}{\hat{u}} \\
\frac{\hat{t}_1}{\hat{t}_2} \rightarrow x_2 \frac{\hat{t}_1}{\hat{t}_2}
\end{array} \right)\).
and we need the additional LO splitting functions

\[
P_{qq} = P_{qq} = T_j \left[ x^2 + (1 - x)^2 \right], \quad \Delta P_{qq} = \Delta P_{qq} = T_j (2x - 1),
\]

where \( T_j = 1/2 \) and we see compared to (6.12) the usual factor \( 1/(2N_C) \). Finally for NLO quark-antiquark annihilation in hadroproduction we have Fig. 6.3 (d) and similarly for the other incoming leg, so that we have to subtract

\[
\frac{d^2 \sigma_{\text{NLO}}^{(1)}}{d t_1 d u_1}(\mu_1^2, \mu_2^2) = \int_0^1 dx_1 x_1 G_{qq}(x_1, \mu_1^2, \mu_2^2) \left[ \frac{d^2 \sigma_{\text{LO}}^{(0)}}{d t_1 d u_1} \right] \left( s \rightarrow x_1 s \right) \left( u_1 \rightarrow x_1 u_1 \right)
+ \int_0^1 dx_2 x_2 G_{\bar{q}q}(x_2, \mu_1^2, \mu_2^2) \left[ \frac{d^2 \sigma_{\text{LO}}^{(0)}}{d t_1 d u_1} \right] \left( s \rightarrow x_2 s \right) \left( t_1 \rightarrow x_2 t_1 \right).
\]

with the appropriately regulated LO splitting function

\[
P_{qq} = P_{\bar{q}q} = C_F \left[ \theta(1 - x - \delta) \frac{1 + x^2}{1 - x} + \delta(1 - x) \left( 2 \ln \delta + \frac{3}{2} \right) \right],
\]

\[
\Delta P_{qq} = \Delta P_{\bar{q}q} = P_{qq} + P_{\bar{q}q}^{\text{HVBM}}.
\]

Here we encounter the problem of the HVBM scheme [54], that helicity conservation at the \( q\bar{q}q \)-vertex is violated due to the commuting \( \gamma_5 \) in the extra \( \varepsilon \)-dimensions, as was already mentioned in Chap. 2 and also discussed below (6.16). Thus actually the collinear singularities in the polarized quark-antiquark annihilation do not appear in conjunction with \( \Delta P_{qq} = P_{qq} \), as they should. If helicity were conserved, then splitting that mixes helicities would be forbidden and hence the piece with mixed helicities, which is added in the unpolarized and subtracted in the polarized case, would be zero, leading to identical splitting functions. The HVBM violating effect is naturally of \( \mathcal{O}(\varepsilon) \), but together with the collinear pole this will give rise to finite contributions. However, since we are eliminating the collinear contributions anyway by a redefinition of the parton densities, we can remove this unphysical property of the HVBM scheme by simply subtracting this finite contribution together with the poles. So we simply chose for \( P_{qq}^{\text{HVBM}} \) not the physical value zero, but rather the value it has in the HVBM scheme, see [27]:

\[
P_{qq}^{\text{HVBM}} = -\theta(1 - x - \delta) 2C_F (n - 4) (1 - x) = -\theta(1 - x - \delta) 2C_F \varepsilon (1 - x),
\]

and thereby restore helicity conservation.

To finish this section, we note that after mass factorization all reduced cross sections will be finite. Thus for factors depending on \( \varepsilon \) one can then safely perform the \( \varepsilon \rightarrow 0 \) limit. Examining the factor (6.5) and our choice for the MS factorization scheme in (6.16), it is easy to see that the former pure pole parts are converted to finite parts in the reduced cross sections by

\[
F_\varepsilon \tilde{G}_\varepsilon \rightarrow \frac{1}{s^2}, \quad E_\varepsilon \rightarrow 1, \quad \text{and} \quad \frac{2}{\varepsilon} \rightarrow \ln \frac{s_4^2}{m^2 (s_4 + m^2)} - \ln \frac{\mu_j^2}{m^2},
\]

so one can easily obtain these contributions from the pole parts we will quote.
Chapter 7

Parton Level Results

7.1 Photon-(Anti)Quark Scaling Functions

We will now present our results for the different subprocesses on a parton level, i.e., we will present the appropriate reduced partonic cross sections. As has been explained in the last chapter, these will have to be convoluted with the dressed parton distribution to obtain hadronic cross sections and thus physical predictions. Interesting phenomenological applications will be examined in the next chapter. However, the convolution with the parton distribution functions makes it difficult to distinguish characteristic features of the reduced partonic cross sections themselves, so it is worthwhile to consider them on their own. In particular we will consider the total reduced partonic cross sections. That means, we have to integrate our double differential results, see (2.24) and (5.19), over the possible range of the partonic variables $t_1$ and $u_1$ to obtain “total” results. The reason is the following: we expect the cross section to depend logarithmically on the renormalization and factorization scale, due to (4.56) and (6.15). Furthermore the running $\alpha_s$ also depends logarithmically on $\mu_r$, see (4.38). Let us concentrate on the factors multiplying these logarithms and $\alpha_s$. When we integrate out $t_1$ and $u_1$, to obtain the total cross section, the only scales left will be the partonic center-of-mass energy $s$ and the heavy quark mass $m$. We find that the total cross section is $\sim 1/m^2$, i.e., we see the expected divergence of the total cross section for $m \to 0$. If we take this factor out as well, then what is left must be dimensionless and hence can be rewritten in some scaling variable depending only on $s/m^2$. We will call these remaining expressions scaling functions and the form we give for the total cross section (7.2) below makes this scaling explicit. The usefulness of the scaling functions is simply that we can use them to display our results without specifying $s$ and $m$.

In order to obtain the total partonic cross section, we must first consider the kinematic boundaries of the $t_1,u_1$-integrations. From the positivity of the energy of the third particle $\omega_3 \geq 0$, we get $s_4 = s + t_1 + u_1 \geq 0$. In the true $2 \to 2$ cross sections (2.22), $s_4$ is equal to zero due to energy-momentum conservation. It is sufficient to consider only the $2 \to 2$ phase space, in the case of $2 \to 3$ this corresponds to the effective $2 \to 2$ of (5.16), to find
the limits of the $t_1$ and $u_1$ integrations. We have

$$t_1 = -\sqrt{s}(E_2 + |\vec{p}_z| \cos \xi), \quad u_1 = -\sqrt{s}(E_2 - |\vec{p}_z| \cos \xi),$$

so we know that $t_1$ and $u_1$ are negative. Thus $s > s_4$ and from $\vec{p}_z^2 \geq 0$ we find the threshold condition $s \geq 4m^2$. Obviously extreme values of $t_1$ and $u_1$ are obtained for $\cos \xi = \pm 1$. Using (7.1), we find $u_1 - t_1 = \cos \xi \sqrt{(t_1 + u_1)^2 - 4m^2s}$, so by squaring we directly get $t_1u_1 \geq m^2s$. Now we have two constraints, which we can solve for $-u_1$ to get $-m^2s/t_1 \leq -u_1 \leq s + t_1$. This can serve as an inner integration range of $u_1$ depending on $t_1$. For the true $2 \to 2$ processes $-u_1$ is exactly at the upper limit. We get next the range of the integration over $t_1$ directly from the intersection of the $u_1$ limits:

$$-m^2s/t_1 \leq s + t_1.$$ 

This yields $s(1 - \beta)/2 \leq -t_1 \leq s(1 + \beta)/2$, with $\beta \equiv \sqrt{1 - 4m^2/s}$. The (reduced) total partonic cross sections can then be expressed in terms of scaling functions in both the unpolarized and polarized case $(l, m = g, q, \bar{q}, \gamma) [43, 46, 34]$

$$\hat{\sigma}_{lm}(s, m^2, \mu_f^2, \mu_r^2) = \frac{\alpha^2 \alpha_s^k(\mu_r^2)}{m^2} \left\{ \mathcal{Z}_{l_m}^{(0)}(\eta) + 4\pi \alpha_s(\mu_r^2) \left[ \mathcal{Z}_{l_m}^{(1)}(\eta) + \mathcal{Z}_{l_m}^{(1)}(\eta) \ln \frac{\mu_f^2}{m^2} \right] \right\} ,$$

$$\beta = \sqrt{1 - \frac{4m^2}{s}} = \sqrt{\frac{\eta}{1 + \eta}}, \quad \eta = \frac{s}{4m^2} - 1 = \frac{\beta^2}{1 - \beta^2},$$

where $k = 1$ for photon- and $k = 2$ for hadroproduction. We have introduced the variable $\eta$ in (7.3), since it will be particularly convenient for showing both the approach to threshold $\eta \to 0$ and high energy $\eta \to \infty$ in logarithmic plots of the scaling functions. The scaling functions $\mathcal{Z}_{l_m}^{(0)}$ and $\mathcal{Z}_{l_m}^{(1)}$ stand for the LO and NLO corrections, respectively.

We have not written a $\ln(\mu_r^2/m^2)$ piece in (7.2), though it of course exists. But we can extract the renormalization logarithms from (4.56):

$$d\hat{\sigma}_r^{(1)} = d\hat{\sigma}_r^{(1)} + k \alpha_s \frac{\beta_0}{4\pi} \left[ \frac{2}{\varepsilon_m} - \frac{2}{3} \frac{2}{\varepsilon_m} \right] d\hat{\sigma}_r^{(0)},$$

with $d\hat{\sigma}_r^{(0)} \sim \alpha_s^k$ and $\beta_0 = (11C_A - 2n_f)/3$. The general form of the UV singularities of the virtual contributions is $\sim C_2 \varepsilon^2$, i.e., in (3.5) the integral will give a pole $\sim 1/\varepsilon$ and there is an overall factor $C_2$ in front. For the UV renormalization we do not have to worry about double poles $\sim 1/\varepsilon^2$ that can occur in our loop integrals, since they only come from the infrared plus collinear limit. Note that $C_2 \varepsilon^2 \sim \frac{2}{\varepsilon_m} + \mathcal{O}(\varepsilon)$, with

$$\frac{2}{\varepsilon_m} = \frac{2}{\varepsilon} + \ln \frac{\mu_r^2}{m^2} = \frac{2}{\varepsilon} + \gamma_E - \ln(4\pi) - \ln \frac{\mu_r^2}{m^2}.$$ 

\footnote{Note that we still use the “tilde notation” as a shorthand to denote both the longitudinally polarized and unpolarized cross sections simultaneously.}
The counterterm of (7.4) will cancel the $2/\varepsilon$ poles, so they must come in the form

$$-k \frac{\alpha_s}{4\pi} \left[ \beta_0 \frac{2}{\varepsilon_m} - \frac{2}{3} \frac{2}{\varepsilon_m} \right] d\hat{\sigma}^{(0)},$$

where we however always have $\frac{2}{\varepsilon_m}$ due to $C_\varepsilon$. We can ignore all common factors, even when they depend on $\varepsilon$ like $F_\varepsilon$, since after the cancellation of these singularities only soft and collinear ones remain, which will not yield renormalization logarithms. Summing both contributions, we get

$$k \frac{\alpha_s}{4\pi} \beta_0 \left( \frac{2}{\varepsilon} - \frac{2}{\varepsilon_m} \right) d\hat{\sigma}^{(0)} = k \frac{\alpha_s}{4\pi} \beta_0 \ln \frac{\mu^2}{m^2} d\hat{\sigma}^{(0)},$$

We chose to rewrite the renormalization logarithm as $\ln(\mu^2/m^2) \rightarrow \ln(\mu^2/\mu_f^2) + \ln(\mu_f^2/m^2)$ and absorb the $\ln(\mu_f^2/m^2)$ contribution in $\tilde{f}_{1m}^{(1)}$ of (7.2). This is convenient in particular for the cases where the splitting function $\tilde{P}_{gg}$ appears in the factorization, since the $\beta_0$
7.1. Photon-(Anti)Quark Scaling Functions

term in the soft $\delta(1-x)$ part, see (6.28), exactly cancels this contribution. At any rate, keeping in mind that the $k$ in (7.7) comes from the power of $\alpha_s$ in the Born cross section, we can get the renormalization log contribution missing in (7.2) by setting

$$\alpha_s(\mu_r^2) \to \alpha_s(\mu_r^2) \left(1 + \alpha_s(\mu_r^2) \frac{\beta_0}{4\pi} \ln \frac{\mu_r^2}{\mu_f^2}\right) ,$$

(7.8)

and keeping only NLO terms. So in our case we have

$$\bar{f}_{1m}^{(1)}(\eta) \to \bar{f}_{1m}^{(1)}(\eta) + \frac{k \beta_0}{16\pi^2} \bar{f}_{1m}^{(1)}(\eta) \ln \frac{\mu_r^2}{\mu_f^2} ,$$

(7.9)

where again $k = 1$ for photo- and $k = 2$ for hadroproduction. So we see that the contribution depending on the ratio of the factorization and renormalization scale does not require a new scaling function and is furthermore easily derivable. Thus we will not worry about it any further in this chapter.

We have already performed the calculation of the photon-light quark contribution, including its factorization, in the last chapter so we can now immediately obtain the scaling functions. Part of the finite reduced quark cross section can be obtained by applying (6.36) to (6.3). Our results fully agree with [46] in the unpolarized case. There is no LO contribution, and thus $\bar{f}_{1m}^{(0)} = 0$. Note that we have only calculated the contribution for the production of a heavy antiquark. But we can split up the squared matrix elements of photo- and hadroproduction in parts that are symmetric $|\tilde{M}_3^2(p_2, p_1) = |\tilde{M}_3^2(p_1, p_2)$ and antisymmetric $|\tilde{M}_3^2(p_2, p_1) = -|\tilde{M}_3^2(p_1, p_2)$ with respect to exchanging $p_1 \leftrightarrow p_2$, respectively. However, applying $p_1 \leftrightarrow p_2$ to the phase space integrations means that instead of the heavy quark $p_1$ one integrates out the heavy antiquark $p_2$ (plus a gluon $k_3$ in both cases in the $2 \to 3$ processes), i.e., the heavy quark is observed. So we can directly apply $p_1 \leftrightarrow p_2$ to the double differential partonic cross sections for heavy antiquark production to obtain those for heavy quark production

$$\frac{d^2\sigma(t_1, u_1)}{dt_1 du_1} \equiv \int d^n p_1 \left[|\tilde{M}_3^2(p_1, p_2) + |\tilde{M}_3^2(p_1, p_2)\right]$$

$$= \int d^n p_1 \left[|\tilde{M}_3^2(p_1, p_2) + |\tilde{M}_3^2(p_1, p_2)\right] \sim \frac{d^2\sigma^Q(t_1^Q, u_1^Q)}{dt_1^Q du_1^Q} ,$$

(7.10)

i.e., the sign of the antisymmetric part changes. But one has to keep in mind that now $t_1$ and $u_1$ are taken with respect to the observed heavy quark $p_1$ instead of the heavy

\footnote{One has to keep in mind though, that in the quark-antiquark case we are absorbing $\beta_0$ terms in $\tilde{f}_{1m}^{(1)}$, which normally would be absent.}
antiquark $p_2$, as it was in (5.12). This redefinition is always implied for quark production in the following, i.e., we will write $t_1$ and $u_1$ also there. For the $2 \to 2$ processes there is of course no difference between these definitions. In the case at hand, $\hat{A}_1$ and $\hat{A}_2$ in (6.3) stay unchanged for $p_1 \leftrightarrow p_2$, whereas $\hat{A}_3$ changes sign. Thus if one wants to observe a heavy quark instead of a heavy antiquark, one can use $[c_Q^2 \hat{A}_1 + c_Q^2 \hat{A}_2 - e_Q c_Q \hat{A}_3]$ in (6.2) with the same expressions for the $\hat{A}_i$ [46].

In addition charge conjugation gives us even more information, since we have a light quark in the initial and final state

$$\frac{d^2 \hat{\sigma}}{dt_1 du_1} \left( \gamma q \to \overline{Q} \right) = \frac{d^2 \hat{\sigma}}{dt_1 du_1} \left( \gamma q \to Q \right) \quad \text{and} \quad \frac{d^2 \hat{\sigma}}{dt_1 du_1} \left( \gamma \overline{q} \to Q \right) = \frac{d^2 \hat{\sigma}}{dt_1 du_1} \left( \gamma q \to \overline{Q} \right).$$

(7.11)

Thus one can use the same $\hat{A}_i$ for the contribution due to an incoming antiquark in (6.1) as well, taking into account a negative sign for $\hat{A}_3$ again [46]. Note that the sign change of $\hat{A}_3$ also implies that $\hat{A}_3$ does not contribute to the total cross section (7.2), since the result

Figure 7.2: The NLO polarized and unpolarized “Compton” scaling functions $\tilde{d}_{\gamma q}^{(1)}$ and $\tilde{\delta}_{\gamma q}^{(1)}$ in the $\overline{\text{MS}}$ scheme as function of $\eta$ as defined in (7.12). The unpolarized scaling functions have been divided by 2.
cannot depend on whether the heavy quark or heavy antiquark is integrated first. This is also expected from Furry’s theorem, which can be applied to the interference term if we integrate over the complete phase space. So there will be no scaling function \( \sim c_q c_Q \) and the scaling function \( \tilde{\bar{f}}_{\eta q}^{(1)} \) can be written as the sum of the “Bethe-Heitler” contribution \( \bar{g}_{\eta q}^{(1)} \) and the “Compton” contribution \( \bar{d}_{\eta q}^{(1)} \)

\[
\tilde{\bar{f}}_{\eta q}^{(1)}(\eta) = e_Q^2 \bar{g}_{\eta q}^{(1)}(\eta) + e_q^2 \bar{d}_{\eta q}^{(1)}(\eta),
\]

and similarly for the “bar” scaling function \( \tilde{\bar{g}}_{\eta q}^{(1)} \). There is no LO scaling function, of course. We plot \( \bar{g}_{\eta q} \) in Fig. 7.1 and \( \bar{d}_{\eta q} \) in Fig. 7.2. In both cases the solid line represents the NLO polarized, the dot-dashed line the NLO polarized “bar”, the dashed line the NLO unpolarized and the dotted line the NLO unpolarized “bar” scaling function. The unpolarized scaling functions have been divided by a constant factor in order to fit into the same plot.

We see that the form of the unpolarized and corresponding polarized scaling functions differs quite strongly. What one cannot see in the plots, because the functions become small and because the unpolarized ones have been divided by a factor, is that for \( \eta \to 0 \) the scaling functions have the behavior \( \Delta \bar{c}_{\eta q}^{(1)} \to c_{\eta q}^{(1)} \), \( \Delta \bar{d}_{\eta q}^{(1)} \to -\bar{d}_{\eta q}^{(1)} \), and similarly for the “bar” scaling functions. By inspecting

\[
\tilde{\bar{c}} = \frac{1}{2} \tilde{\bar{c}}(++) + \tilde{\bar{c}}(+-), \quad \Delta \tilde{\bar{c}} = \frac{1}{2} \tilde{\bar{c}}(++) - \tilde{\bar{c}}(+-),
\]

we conclude that for \( \eta \to 0 \) in the “Bethe-Heitler” \( \bar{c}_{\eta q}^{(1)} \) part of the partonic cross section \( \tilde{\bar{c}}(+-) \to 0 \), whereas in that limit for the “Compton” \( \bar{d}_{\eta q}^{(1)} \) part we find \( \tilde{\bar{c}}(++) \to 0 \). Or more precisely - that one helicity combination goes faster to zero than the other. On the other hand for \( \eta \to \infty \), we find \( \bar{c}_{\eta q}^{(1)} \) becomes constant whereas \( \Delta \bar{c}_{\eta q}^{(1)} \to 0 \) and the same happens for the “bar” functions, implying \( \tilde{\bar{c}}(++) \to \tilde{\bar{c}}(+-) \) for the “Bethe-Heitler” process. For the “Compton” process we find no obvious high energy limit of the partonic cross sections numerically. The observed plateau in the unpolarized \( \bar{c}_{\eta q}^{(1)} \) is due to a flavor excitation process, in which a t-channel gluon is exchanged in the subprocess \( Q^* q \to Q q \), and the virtual heavy quark is produced in \( \gamma \to Q^* Q \) first, and similarly for the heavy virtual antiquark, compare Fig. 6.1 (a) and (b).

### 7.2 Photon-Gluon Scaling Functions

Next we turn to the NLO corrections to the PGF process (2.17)

\[
\tilde{\gamma}(k_1) + \tilde{\bar{g}}(k_2) \to Q_i(p_1) + \overline{Q_j}(p_2),
\]

where one-loop virtual and gluon bremsstrahlung contributions have to be taken into account. We start with the one-loop virtual corrections displayed in Fig. 7.3. They are calculated by the methods of Chap. 3. Remember that they have the same 2 \( \to 2 \).
Figure 7.3: The NLO virtual corrections to $\gamma g \rightarrow Q\bar{Q}$. Reversing the heavy quark lines, except for the non-planar graph (b), yields the remaining graphs. Massless particle loops similar to graph (i) vanish, similarly to (3.3).

kinematics as the LO reaction (7.14) and thus can be calculated using (2.18) and (2.24). As mentioned, at $\mathcal{O}(\alpha\alpha_s^2)$ only the interference between the virtual $V$ and Born $B$ amplitudes of Fig. 7.3 and Fig. 2.2 contributes

$$|\tilde{M}|^2_{V,B} = 2\text{Re} \left( \tilde{M}_V \tilde{M}_B^* \right) = E g^4 e_Q^2 \left[ 2 C_F \tilde{V}_{QED} + C_A \tilde{V}_{OK} \right],$$

(7.15)

where all quantities with a tilde denote as always, both the unpolarized and polarized expressions, e.g., $\tilde{V}_{QED}$ denotes either $V_{QED}$ or the spin-dependent $\Delta V_{QED}$. The results have been sorted according to the color-factors $2C_F$ and $C_A$. We will not show the reduced virtual cross sections because of their length, but they can be reconstructed from the virtual plus soft cross sections discussed later. We note that $\tilde{V}_{QED}$, which receives contributions only from the graphs (a), (c), (d) and (f)-(h) in Fig. 7.3, corresponds to the process where the gluon is replaced by a photon in the initial state, i.e., $\gamma \gamma \rightarrow Q\bar{Q}$. Complete NLO QCD $\mathcal{O}(\alpha^2\alpha_s)$ calculation of this process have been performed recently in [60] for both the unpolarized and polarized case. Our NLO results for the QED-part of $\gamma g \rightarrow Q\bar{Q}$ agree analytically with the ones presented in [60].
7.2. Photon-Gluon Scaling Functions

Each fermion propagator and each triple-gluon vertex in the loop introduces a loop momentum $q^\mu$ in the numerator. A glance at Fig. 7.3 then reveals that the maximal number of loop momenta we face in the numerator is one less than the number of propagators, except for graph (i). In particular, one has to deal with tensor four-point integrals of first $(q^\mu)$ to third $(q^\mu q^\nu q^\rho)$ order and with tensor three- and two-point integrals of first $(q^\mu)$ and second $(q^\mu q^\nu)$ order. We use our program, described in Chap. 3, to reduce these tensor integrals to a set of scalar ones by using an adapted Passarino-Veltman decomposition method [47]. This accounts properly for all possible $n$-dimensionally regulated divergences in QCD. For graph (i) we need (3.51). In the results ultraviolet (UV), infrared (IR) and collinear/mass (M) singularities show up as $1/\varepsilon$ poles. In the non-abelian “OK”-part also double poles $1/\varepsilon^2$ occur when IR and M singularities coincide. The UV divergences are removed by the renormalization procedure of Chap. 4. The IR and IR+M singularities cancel against the soft part of the gluon bremsstrahlung, which we will derive below. A left over M singularity cancels against the soft $\delta(1-x)$ part of $\tilde{P}_{gg}$, see (6.28), when we obtain the reduced bremsstrahlung cross section using (6.27) in the mass factorization procedure.

![Feynman diagrams](image)

Figure 7.4: Feynman diagrams for the NLO gluon bremsstrahlung process $\gamma g \to Q\bar{Q}g$. Reversing the heavy quark lines yields the remaining graphs. In the unpolarized calculation the ghost contributions (e) and (f) have to be subtracted to cancel unphysical polarization contributions, see Fig. 2.1 and App. B.4.

In order to be able to present finite results, we will thus first calculate the corresponding real gluon emission reactions as well. The corresponding Feynman diagrams are shown in Fig. 7.4 and the momentum and color assignment is

$$\gamma(k_1) + g^a(k_2) \to Q_i(p_1) + \bar{Q}_j(p_2) + g^b(k_3). \quad (7.16)$$
The techniques for handling these graphs, in particular our program for automatic partial fractioning of the angular integrals, have been explained in detail in Chap. 5. The squared matrix element, to be inserted in (5.19), can again be split into an abelian and a non-abelian part like (7.15)

\[
|M_R|^2 = M_R^p M_R^0 = E_e^2 g^A e^2 e_Q^2 \left[ 2C_F \tilde{R}_{\text{QED}} + C_A \tilde{R}_{\text{OK}} \right].
\]  

(7.17)

We use the phase space slicing of Sec. 5.4 to isolate the hard and soft parts. The collinear pole part of the hard photon-gluon cross section then becomes

\[
\left( \frac{d^2 \tilde{\sigma}^{(1)}_{g,\text{OK}}}{dt_1 dt_2} \right)^H = C_A F_\gamma^H G_\gamma^H E_e^2 \alpha_s^2 \alpha e_Q^2 \tilde{H}_\text{QED}^\text{pole} + O(1),
\]

(7.18)

\[
\tilde{H}_\text{QED}^\text{pole} = -\frac{1}{u_1} \left[ \frac{1}{1-x_2} + \frac{1}{x_2} - 2 - x_2(1-x_2) \right] \cdot \left\{ \frac{x_2 t_1}{u_1} + \frac{u_1}{x_2 t_1} + \frac{4m^2(x_2 s)}{(x_2 s) u_1} \left[ 1 - \frac{m^2(x_2 s)}{(x_2 s) u_1} \right] \right\},
\]

(7.19)

\[
\Delta H_\text{QED}^\text{pole} = -\frac{1}{u_1} \left[ \frac{1}{1-x_2} - 2x_2 + 1 \right] \left\{ \frac{x_2 t_1}{u_1} + \frac{u_1}{x_2 t_1} \right\} \left[ \frac{2m^2(x_2 s)}{(x_2 s) u_1} - 1 \right],
\]

(7.20)

where only the non-abelian “OK” part is shown, because the hard abelian “QED” part is completely finite. \( G_\gamma^H \) is defined in (6.5) and \( x_2 \) in (6.4). As expected, we find the form necessary for the mass factorization in (6.27), see the hard \( \Theta(1-x-\delta) \) part of (6.28). The finite contributions are too long to be presented here in an analytical form, but they can be found in our computer program, which is available upon request. Remember that one can extract the finite rest of the pole part in (7.18) after mass factorization, by applying (6.36). Our unpolarized results agree with those of [46].

We now turn to the soft gluon emission. According to the discussion in Sec. 5.4, we only need to isolate the \( 1/s_4^2 \) poles of the squared matrix element by applying (5.23) and (5.24). In this way one can easily derive the soft limit of \( \tilde{R}_{\text{QED}} \) and \( \tilde{R}_{\text{OK}} \) in (7.17)

\[
\tilde{S}_{\text{QED}} = -\frac{2}{s_4^2} \left[ m^2 \left( 1 + \frac{1}{s_4^2} \right) + \frac{(2m^2 - s)}{s_4^2} \right] \tilde{B}_{\text{QED}},
\]

(7.21)

\[
\tilde{S}_{\text{OK}} = \frac{2}{s_4^2} \left[ \frac{1}{t_1} \left( \frac{t_1}{s_4^2} + u_1 \right) + \frac{(2m^2 - s)}{s_4^2} \right] \tilde{B}_{\text{QED}},
\]

(7.22)

using the polarized and unpolarized \( \Delta B_{\text{QED}} \) and \( B_{\text{QED}} \) given in (2.21), respectively. We agree again in the unpolarized case with [46]. The soft cross section is obtained from (7.21) and (7.22) with the \( 1/s_4^2 \) replaced by \( \delta(s_4) \Delta /\varepsilon \) according to (5.65) and (5.66). Using this replacement and performing the angular integrations \( d\Omega_\varepsilon \) the soft gluon
cross section is then given by
\[
\left( \frac{d^2 \hat{\sigma}^{(1)}_{\gamma g, QED}}{d t \, d u} \right)^{\gamma g} = 2 C_F F_2^2 \alpha_s^2 \alpha_s \alpha_s^2 \frac{\hat{B}_{QED}}{Q} \sum \left( -\frac{2}{\varepsilon} + 1 + \frac{2 m^2 - s}{s \beta} \ln \frac{\varepsilon}{S(\varepsilon)} \right) \delta(s_4),
\]
(7.23)

\[
\left( \frac{d^2 \hat{\sigma}^{(1)}_{\gamma g, QED}}{d t \, d u} \right)^{\gamma g} = C_A F_2^2 \alpha_s^2 \alpha_s^2 \alpha_s^2 \frac{\hat{B}_{QED}}{Q} \sum \left( -\frac{4}{\varepsilon^2} + \frac{2}{\varepsilon} \ln \frac{t_1}{u_1} + \ln \frac{t_1}{u_1} + \frac{1}{2} \ln^2 \frac{t_1}{u_1} - \frac{1}{2} \ln^2 \varepsilon \right)
+ \frac{2 m^2 - s}{s \beta} \ln \frac{\varepsilon}{S(\varepsilon)} \delta(s_4),
\]
(7.24)

with \( \hat{B}_{QED} \) defined in (2.21) and
\[
S(\varepsilon) \equiv -\frac{2}{\varepsilon} \ln \varepsilon + \text{Li}_2(\varepsilon^2) - \ln^2 \varepsilon + 2 \ln \varepsilon \ln(1 - \varepsilon^2) - \zeta(2),
\]
(7.25)
\[
G^S_\alpha \equiv 4(4\pi)^3 C_F \frac{3}{8} \zeta(2) \varepsilon^2 \left( \frac{\Delta}{m^2} \right)^{\varepsilon} \equiv \frac{2(4\pi)^4 m^2 \varepsilon}{s^4} G^S_\alpha,
\]
(7.26)

where we have used \( \varepsilon \equiv (1 - \beta)/(1 + \beta) \), the dilogarithm function \( \text{Li}_2 \) as defined in App. B.2, and the Riemann zeta function \( \zeta(2) = \pi^2/6 \). Our unpolarized results for the soft bremsstrahlung cross section are again identical to those of [46]. In addition we have checked that the abelian “QED” part of the polarized (and unpolarized) total bremsstrahlung cross section is in complete analytical agreement with the NLO expressions for \( \gamma\gamma \to Q\bar{Q} \) presented in [60].

To complete the calculation of the photon-gluon cross section, we now add the \( \delta(1 - x) \) mass factorization contribution from (6.27), see (6.29), to the renormalized virtual plus soft part virtual plus soft part \( V + S \). We write the result in three parts using the usual abelian and non-abelian split and, in addition, separating off the part\(^3\) proportional to \( \beta_0 \). The latter piece vanishes if one identifies the renormalization scale with the factorization scale, \( \mu_r = \mu_f \), as is usually done, and corresponds to the \( \alpha_s \) redefinition of (7.8):
\[
\left( \frac{d^2 \hat{\sigma}^{(1)}_{\gamma g, QED}}{d t \, d u} \right)^{V+S} = \frac{\alpha_s^2 \alpha_s Q}{s^2} \left[ 2 C_F \left( \hat{L}_{\text{QED}} + \hat{L}_{\Delta \text{QED}} \right) + C_A \left( \hat{L}_{\text{OK}} + \hat{L}_{\Delta \text{OK}} \right) + \frac{\beta_0}{4} \hat{I}_{\text{RF}} \right] \delta(s_4).
\]
(7.27)

The \( \hat{L}_{\Delta} \) explicitly depend on the auxiliary cutoff \( \Delta \). The polarized \( \Delta L \) are presented in App. C and the unpolarized \( L \) are in complete agreement with those obtainable from App. A of [46] and App. D of [44]. The treatment of the \( \hat{L}_{\Delta} \) terms has been discussed in Sec. 5.4. Both for numerical stability and in order to be able to present the \( V + S \) and \( H \)

\(^3\)The factor 1/2 compared with the expression in [35] is compensated by the squares in the logarithm of (C.11).
Figure 7.5: The NLO polarized and unpolarized scaling functions $\tilde{c}_{1g}$ in the $\overline{\text{MS}}$ scheme as function of $\eta$ as defined in (7.28). The “bar” scaling functions $\tilde{\tilde{c}}_{1g}$ are also shown.

parts separately in the plots, we shift the $\ln k^2 \Delta / m^2$ terms with $k = 1, 2$ from the $V + S$ to the $H$ part. So written symbolically, the meaning of soft and hard is “soft” = $S + V - \Delta$ and “hard” = $H + \Delta$, respectively. Note that again the presented results have been calculated for a detected heavy antiquark in the final state, because the heavy quark was integrated out in the calculations. Due to the $p_1 \leftrightarrow p_2$ symmetry of the matrix elements, the same double differential photon-gluon cross section can be used for a detected heavy quark as well [46]. Only then $t_1$ and $u_1$ are defined with respect to the observed heavy quark, see (7.10). On the other hand there is an asymmetry in the non-abelian part of the photon-gluon cross section with respect to $k_1 \leftrightarrow k_2$, since the outgoing gluon with momentum $k_3$ can only “couple” to the incoming gluon with momentum $k_2$, but not to the photon with momentum $k_1$. So the photon-gluon cross section is $t_1 \leftrightarrow u_1$ asymmetric.

The scaling functions for photon-gluon have the form

$$\tilde{f}_{\gamma \rightarrow q}(\eta) = e_Q^2 \tilde{c}_{\gamma q}(\eta),$$

(7.28)

which is valid for LO, NLO and for the “bar” scaling functions $\tilde{\tilde{c}}_{1g}$ as well. In Fig. 7.5 we display the NLO scaling functions. Again the solid line represents the NLO polarized,
the dot-dashed line the NLO polarized "bar", the dashed line the NLO unpolarized and the dotted line the NLO unpolarized "bar" scaling function. In Fig. 7.6 we show the LO polarized (solid line) and unpolarized (dot-dashed line) scaling functions, as well as the combination $\tilde{c}^{(0)}_{g} + 2.7\tilde{c}^{(1)}_{g}$ in the polarized (dashed line) and unpolarized case (dotted line). The reason for showing this particular combination is that $4\pi\alpha_s(m^2) \simeq 2.7$ for charm production at COMPASS [31], where our photoproduction cross section will be mainly used. We see from (7.2), that in order to obtain an estimate of the size of the corrections LO $\tilde{J}_{lm}^{(0)}$ and NLO $\tilde{J}_{lm}^{(0)} + 4\pi\alpha_s\tilde{J}_{lm}^{(1)}$ should be compared with each other.

The form of the unpolarized and polarized scaling functions again differs quite strongly. This time we can see directly that the scaling functions have in LO and in NLO the behavior $\Delta c_{g} \rightarrow c_{g}$ for $\eta \rightarrow 0$, and similarly for the "bar" scaling functions. Thus we can conclude using (7.13), that as $\eta \rightarrow 0$ the PGF partonic cross section $\hat{\sigma}(+\pm) \rightarrow 0$. In LO this means that one helicity combination goes faster to zero than the other, but in NLO actually $\hat{\sigma}(++)$ becomes a non-zero constant in the $\eta \rightarrow 0$ limit. The reason for this is on one hand the graph Fig. 7.3 (a). Close to threshold the corresponding matrix
Figure 7.7: The soft \( (V + S - \Delta) \), hard \( (H + \Delta) \), non-abelian (OK), and abelian (QED) parts of the NLO polarized scaling function \( \Delta c_{\gamma g}^{(1)} \) in the \( \overline{\text{MS}} \) scheme as function of \( \eta \). Soft+hard and OK+QED will both give \( \Delta c_{\gamma g}^{(1)} \) of Fig. 7.5.

The element diverges \( \sim 1/\beta \), which corresponds to a Coulomb singularity for the heavy quark-antiquark pair produced in close proximity and almost at rest. This becomes suppressed by phase space integration \( \sim \beta \), and one ends up with a non-zero constant at threshold. The LO matrix element does not diverge close to threshold since there is no interaction between the produced heavy quark and heavy antiquark, compare Fig. 2.2, and so due to the phase space the LO partonic cross section goes to zero. On the other hand soft gluon emission from the diagrams in Fig. 7.4 actually enhances the “hard” cross section at threshold, since we have shifted the \( \ln^k(\Delta/m^2) \) terms. Looking for example at \( \mathcal{A}_1 \) in (5.68), we see that it does cancel a \( 1/s_4 \) soft \( s_4 \to 0 \) divergence when added to the hard cross section. But it also introduces a finite term, which after integration\(^4 \) over \( s_4 \) results in a \( \ln(s_4^{\text{max}}/m^2) \). Since \( s_4^{\text{max}}/m^2 \sim \beta^2 \) for small \( \beta \), we get together with the phase space

\(^4s_4^{\text{max}}(t_1, u_1)\) occurs for \( t_1u_1 = m^2 s \), so in practice we transform the \( -u_1 \) integration to an \( s_4 \) integration from \( \Delta \) to \( s_4^{\text{max}}(t_1) \) in (7.2). Then the \( \mathcal{A}_i \) depend on \( s_4^{\text{max}}(t_1) = s + t_1 + m^2 s/t_1 \). If we do not transform, then \( s_4^{\text{max}} = s - 2\sqrt{m^2 s} \) with \( t_1 = u_1 = \sqrt{m^2 s} \). We cannot go closer to threshold than \( s_4^{\text{max}} = \Delta \).
suppression a term $\sim \beta \ln \beta^2$. So these remaining logarithms give large contributions up to small values of $\beta$. We can clearly see in Fig. 7.7 both threshold effects: the “soft” part (solid line), containing the Coulomb singularity goes to a constant and the “hard” part (dot-dashed line) containing the remainders of soft gluon emission falls very slowly to zero. Also shown is the separation according to color-factors, the $2 C_F$ “QED” part is displayed as a dashed line and the $C_A$ “OK” part as a dotted line. We see that there are strong cancellations between these two close to threshold: $\Delta c_{qg}^{(1)}(\eta = 0) = (2 C_F - C_A)\pi/32$.

For $\eta \rightarrow \infty$, we find, like for $c_{qg}^{(1)}$, that $\tilde{c}_{qg}^{(1)}$ becomes constant, whereas $\Delta \tilde{c}_{qg}^{(1)} \rightarrow 0$ and the same happens for the “bar” functions. So (7.13) implies $\sigma(++) \rightarrow \sigma(-+)$. The observed plateau in the unpolarized $c_{qg}^{(1)}$ again comes from a flavor excitation process, this time a $t$-channel gluon is exchanged in the process $\overline{Q}g \rightarrow \overline{Q}g$, compare Fig. 7.4 (d), and similarly for the heavy virtual quark in the crossed graph. This appearance of qualitatively new diagrams for the first time in NLO suggests, that really only NLO can be considered to be the first relevant order for this process. The large difference between the “effective” NLO combination and the LO result in Fig. 7.6 is thus no surprise. It is reasonable to expect, that at NNLO we will not see similar drastic changes again, since corrections to the Coulomb singularity, to soft gluon emission and to flavor excitation will be suppressed by $\alpha_s$ and no qualitatively new diagrams appear in NNLO in comparison to NLO. To demonstrate clearly the NLO effects, we display in Fig. 7.8 ratios of the partonic cross sections. To avoid zeroes in the denominator at least in the gluon case, we will use $f_{1m}(++)$ and $f_{1m}(-+)$ instead of $f_{1m}$ and $\Delta f_{1m}$. We show as solid $(++)$ and dot-dashed $(+-)$ lines the ratios of the “effective” NLO to the LO results, e.g., the solid line corresponds to $1 + 2.7 c_{qg}^{(1)}(++)/c_{qg}^{(0)}(++)$. The dashed line represents the absolute value of $2.7[c_{qg}^{(1)}(++) + 0.6 c_{qg}^{(1)}(++)]/[c_{qg}^{(0)}(++) + 2.7 c_{qg}^{(1)}(++)]$ and the dotted line similarly for $(+-)$. These two lines are supposed to give a rough idea\(^5\) of how large the light quark scaling functions are compared to the gluon ones. To explain the crosses with associated $x_{\text{min}}$ values in the plot, note that when we calculate the hadronic photoproduction process by folding in the appropriate parton densities, we will use $s = xS$, where $S$ is the hadronic center-of-mass energy\(^6\). Then

$$\eta = \frac{x}{x_{\text{min}}} - 1, \quad \text{with} \quad \frac{4m^2}{S} \equiv x_{\text{min}} \leq x \leq 1 \quad (7.29)$$

We obviously have $\eta_{\text{max}} = 1/x_{\text{min}} - 1$. So the crosses show the maximally probed $\eta_{\text{max}}$ for different $x_{\text{min}}$. It is also indicated which $\eta$ range the COMPASS experiment [31] will probe with charm photoproduction ($m \approx 1.5$ GeV and $\sqrt{S} \approx 10$ GeV for $E_{\mu} = 100$ GeV).

We see from Fig. 7.8, that the light quark scaling functions only contribute significantly at high energies. There they can reach up to 35% of the gluon scaling functions. The large $\eta$ region is folded with the partons at large $x$, so the light quark contribution will get

---

\(^5\) The factor 0.6 multiplying $c_{qg}^{(1)}(++)$ is a simple minded average of $c_1^2/c_Q = 1/4$ or = 1 for $c_Q = 2/3$.

\(^6\) For photoproduction $f_1(x, \mu_F) = \delta(1 - x_1)$, so that in (6.21) only the $x = x_2$ integration remains, and from $k_1 = x_1 K_1 = K_1$ and $k_2 = x_2 K_2 = x K_2$ we find $s = x_1 x_2 S = xS$. 

enhanced there relative to the gluon one. But for COMPASS energies, we do not expect much “contamination” from the quark sector, unless $\Delta Q$ is very small. We also see, that the high energy NLO enhancements from flavor excitation is irrelevant for COMPASS. We should not be worried by the massive growth of the NLO to LO ratio: LO goes to zero and NLO to a plateau, so obviously the ratio becomes infinite for $\eta \to \infty$. On the other hand COMPASS will see the threshold enhancement from the Compton singularity and from soft gluon bremsstrahlung, in particular since the gluon scaling functions at the smallest $\eta$ will be folded with the gluons at the smallest $x$. However, for COMPASS “small” $x$ are still rather large $x_{\text{min}} \simeq 0.1$ and the factorization scale $\mu_F^2 \simeq m^2 \simeq 2.25$ GeV$^2$ is rather low, so the enhancement due to the rising gluon at small $x$ will not be too strong. Furthermore both helicity combinations are enhanced, so we can expect less changes for the NLO asymmetry ratios of polarized to unpolarized results. For $\eta \to 0$ we indeed see from Fig. 7.6, that at least on the partonic level LO and NLO ratios both become one.
7.3 Gluon-(Anti)Quark and Quark-Antiquark Scaling Functions

![Diagram](image)

Figure 7.9: The only new Feynman diagram appearing in the $\bar{g}q \rightarrow Q\bar{q}_l$ process. The others follow from Fig. 6.1 by replacing the photon by a gluon.

We now turn to the scaling functions for hadroproduction. Our first task will be to compute the scaling functions for the process

$$\bar{g}^a(k_1) + q_j(k_2) \rightarrow Q_k(p_1) + \bar{q}_l(p_2) + q_i(k_3).$$

(7.30)

This is rather simple, since there is only one additional Feynman diagram. It is shown in Fig. 7.9. The other contributions come from the diagrams of Fig. 6.1 with the photon replaced by a gluon, which naturally leads to a more complicated color-structure. Furthermore, of course we have to compute the complete squared matrix element, which includes the interference between the “new” graph and the “old” graphs. We can split up the squared matrix element according to two color-factors:

$$|\tilde{M}_{gg}|^2 = \tilde{M}_{gg}^a \tilde{M}_{gg}^s = E_g g_6^a \frac{1}{8N_C} [2C_F \tilde{J}_{\text{QED}} + C_A \tilde{J}_{\text{OK}}].$$

(7.31)

By inspecting the color-factors of the amplitudes and comparing with (6.2), we can immediately conclude that

$$\tilde{J}_{\text{QED}} = \tilde{A}_1 + \tilde{A}_2 + 2\tilde{A}_3.$$

(7.32)

Thus we do not have to calculate the “QED” part! We can completely construct it from the already known $\tilde{A}_i$.

The pole structure of the “QED” cross section can be obtained from (6.3), and we set $e_g, e_Q \rightarrow 1$ and $e \rightarrow g$ and divide by $1/(2N_C)$ to get the factors right. Note that for the pole part we do not have to worry about the factor two in front of $\tilde{A}_3$, since it is finite and does not appear. Also, as has been mentioned below (7.11), $\tilde{A}_3$ does not contribute to the total cross section. So by defining two color-factor sorted scaling functions as

$$\tilde{f}_{gg}^{(1)}(\eta) = \tilde{f}_{gg,\text{QED}}^{(1)}(\eta) + \tilde{f}_{gg,\text{OK}}^{(1)}(\eta),$$

(7.33)
Chapter 7. Parton Level Results

Figure 7.10: The NLO polarized and unpolarized scaling functions $\tilde{f}_{gq}^{(1)}$ and $\tilde{g}_{gq}^{(1)}$ in the \(\overline{\text{MS}}\) scheme as function of $\eta$. The unpolarized scaling functions have been divided by 45.

corresponding to the parts of the total partonic cross sections that follow from the $J_{\text{QED}}$ and $J_{\text{OK}}$ parts, respectively, we already know that

$$\tilde{f}_{gq,\text{QED}}^{(1)}(\eta) = \frac{1}{2N_C} \left[ \tilde{c}^{(1)}_{gq}(\eta) + \tilde{d}^{(1)}_{gq}(\eta) \right], \quad (7.34)$$

with $\tilde{c}^{(1)}_{gq}$ and $\tilde{d}^{(1)}_{gq}$ defined in (7.12). Once more we get the “usual” factor $1/(2N_C)$ for replacing a photon by a gluon. Analogous expressions to (7.33) and (7.34) are true for the “bar” scaling functions $\tilde{g}_{gq}^{(1)}$.

So we only need to calculate the non-abelian part. Its pole part is given by

$$\frac{d^2\sigma^{(1)}_{gq,\text{OK}}}{dt_1 du_1} = \frac{C_A}{8N_C} F_v G_v E_v^2 \alpha_s^2 \left( \frac{-2(x_2 t_1) u_1}{(x_2 s)^2} \right) \tilde{A}_1^{\text{pole}} + \mathcal{O}(1), \quad (7.35)$$

with $\tilde{A}_1^{\text{pole}}$ as in (6.3). $G_v^H$ is defined in (6.5) and $x_2$ in (6.4). Of course we see that we obtain exactly the necessary form for the mass factorization (6.31), if we compare the newly appearing factor with the $C_A$ part of (2.27). Again we do not quote the rather
lengthy finite parts of both the "QED" and "OK" corrections. Our unpolarized results are in complete agreement with those in [45].

![Graph](image)

Figure 7.11: The non-abelian "OK" parts of Fig. 7.11 associated with the color-factor $C_A$. The abelian "QED" parts with color-factor $2C_F$ can be obtained from (7.34), and thus can be compared to Figs. 7.1 and 7.2.

In Fig. 7.10 we show the corresponding scaling functions, the solid line shows the polarized $\Delta f^{(1)}_{gq}$ and the dot-dashed line shows $\Delta \tilde{f}^{(1)}_{gq}$ for the factorization logarithm. The dashed and dotted lines display the corresponding unpolarized scaling functions, scaled down by a factor 45 in order to fit in the same plot. We see again the behavior, that for $\eta \to \infty$ there is a plateau in the unpolarized part due to flavor excitation, whereas the polarized part goes to zero, so we have $\hat{\sigma}(++) \to \hat{\sigma}(+-)$ for this process. There is however no clean numerical limit for $\eta \to 0$, which is not surprising, since we have here basically a combination of $\tilde{c}^{(1)}_{gq}$ and $\tilde{d}^{(1)}_{gq}$, which have different behaviors in that limit. The role played by the additional $\tilde{f}^{(1)}_{gq,OK}(\eta)$ and the corresponding "bar" functions is examined in Fig. 7.11. The lines show the corresponding non-abelian "OK" parts for the color-factor $C_A$ of the scaling functions plotted in Fig. 7.10. The abelian "QED" part with $2C_F$ is not plotted, since it can be constructed from the $\tilde{c}^{(1)}_{gq}$ and $\tilde{d}^{(1)}_{gq}$, see (7.34). We find that the $\tilde{f}^{(1)}_{gq,OK}(\eta)$ and also the "bar" counterparts share the properties of the $\tilde{c}^{(1)}_{gq}$ and their "bar"
functions with respect to the $\eta$ limits. This is no surprise, since its cross sections are related in form, see (7.35) and (6.3). We see that in the polarized case, the non-abelian parts in Fig. 7.11 are of similar size but quite different shapes compared to the totals in Fig. 7.10, which means that we have strong cancellations with the abelian parts. On the other hand in the unpolarized parts we observe similar shapes, but opposite signs. So there are similar cancellations. Finally we would like to mention, that we can obtain the reduced cross section for the production of a heavy quark instead of a heavy antiquark by switching $p_1 \leftrightarrow p_2$ with $t_1$ and $u_1$ defined with respect to the heavy quark. The behavior of the abelian “QED” part for $p_1 \leftrightarrow p_2$ is clear from the $\gamma q$ case, see (7.32) and the discussion following (7.10). The non-abelian “OK” contribution to heavy antiquark production can be similarly split into the sum of $p_1 \leftrightarrow p_2$ symmetric and antisymmetric parts. Then the heavy quark production contribution is obtained by simply subtracting instead of adding the antisymmetric part. Once more, charge conjugation

$$\frac{d^2 \hat{\sigma}}{dt_1 du_1} (g\bar{q} \rightarrow \bar{Q}) = \frac{d^2 \hat{\sigma}}{dt_1 du_1} (gq \rightarrow Q) \quad \text{and} \quad \frac{d^2 \hat{\sigma}}{dt_1 du_1} (g\bar{q} \rightarrow Q) = \frac{d^2 \hat{\sigma}}{dt_1 du_1} (gq \rightarrow \bar{Q}) \ ,$$

allows us to directly derive the reduced cross section of an incoming light antiquark [43].

Now we turn to the NLO corrections to the process

$$q_j(k_1) + \bar{q}_j(k_2) \rightarrow Q_k(p_1) + \bar{Q}_l(p_2) \ .$$

(7.37)

The needed Feynman diagrams for the virtual corrections, which have the same external momentum and color assignment as the LO process (7.37) and are computed with the $2 \rightarrow 2$ phase space (2.24), are shown in Fig. 7.12. We can separate the squared matrix element of the interference of virtual with Born graphs according to the color factors

$$[\hat{M}_{V,B} = 2 \text{Re} (\hat{M}_{V} \hat{M}_{B}^*) = g^6 \frac{C_F}{4 N_C} \left[ 2 C_F \hat{N}_{QED} + C_A \hat{N}_{OK} + \hat{N}_{QL} \right] ,$$

(7.38)

where the only diagrams contributing to $\hat{N}_{QL}$ are the quark loops of Fig. 7.12 (g). The reduced partonic cross sections can be constructed for each color-part separately. The one following from the quark loop $\hat{N}_{QL}$ is finite after renormalization and yields

$$\left( \frac{d^2 \hat{\sigma}_{g\bar{q},QL}^{(1)}}{dt_1 du_1} \right)^V = \frac{\alpha_s (\mu_r^2)}{3 \pi} \left( - \frac{5(n_f + 1)}{3} - \frac{4 m^2}{s} + n_f \ln \frac{s}{\mu_r^2} - \frac{\beta(s + 2 m^2)}{s} \ln \frac{s}{\mu_r^2} \right) \frac{d^2 \hat{\sigma}_{g\bar{q},LO}}{dt_1 du_1} \ ,$$

(7.39)

where the LO cross section can be read off (2.24) and (2.29) with $\varepsilon \rightarrow 0$. In the unpolarized case this is equivalent to Eqn. (2.15) in [45] upon taking the limit $m_L \rightarrow 0$, where $m_L$ is the mass of the light quarks. We will not show the other reduced virtual cross sections because of their length, but they can be reconstructed from the virtual plus soft cross sections discussed later.
7.3. Gluon-(Anti)Quark and Quark-Antiquark Scaling Functions

Figure 7.12: The NLO virtual corrections to $\bar{q}q \rightarrow Q\bar{Q}$. There are two additional diagrams, one is obtained from reversing the heavy quark lines of graph (a), the other from replacing the gluon loop of graph (f) by a ghost loop. The quark loop of graph (g) has to be computed for massless and massive quarks. Vanishing light quark self-energy loops on the incoming lines, see (3.3), are not shown.

Next we need to calculate the bremsstrahlung process

$$\bar{q}_j(k_1) + q_i(k_2) \rightarrow Q_k(p_1) + Q_i(p_2) + g^n(k_3).$$  \hspace{1cm} (7.40)

The corresponding Feynman diagrams are shown in Fig. 7.13 and lead to a squared matrix element

$$|\tilde{M}_R|^2 = \tilde{M}_R^\dagger \tilde{M}_R = g^n \frac{C_F}{4N_C} \left[ 2C_F \tilde{O}_{QED} + C_A \tilde{O}_{QCD} \right],$$  \hspace{1cm} (7.41)

where we have again sorted according to the occurring color factors. We have calculated these graphs, but in the unpolarized case they can also be obtained from those for the $g\bar{f} \rightarrow Q\bar{Q}f$ process, by crossing $k_3 \leftrightarrow - k_1$ and multiplying with (-1) for crossing a boson and fermion. By crossing and comparing graph by graph, we have a consistency check of our unpolarized results. The collinear pole part of the hard bremsstrahlung cross section
then becomes

\[
\left( \frac{d^2 \tilde{\sigma}_{\text{QED}}^{(1)}}{dt \, du} \right)^H = \frac{C_F}{4N_C} 2 C_F G_\epsilon^H s_s^2 \frac{2 m^2}{\varepsilon} H_{\text{QED}}^{\text{pole}} + O(1) ,
\]

\[
H_{\text{QED}}^{\text{pole}} = \frac{1 + x_2^2}{t_1 - x_1} \left[ \frac{(x_1 u_1)^2}{(x_1 s)^2} + \frac{2 m^2}{x_1 s} \right] - \frac{1 + x_2^2}{u_1 - x_2} \left[ \frac{(x_2 t_1)^2 + u_1^2}{(x_2 s)^2} + \frac{2 m^2}{x_2 s} \right] ,
\]

\[
\Delta H_{\text{QED}}^{\text{pole}} = - H_{\text{QED}}^{\text{pole}} .
\]

where only the abelian “QED” part is shown, because the hard non-abelian “OK” part is completely finite. $G_\epsilon^H$ is defined in (6.5) and $x_1, x_2$ in (6.4). As expected, we find the form necessary for the mass factorization in (6.33), see the hard $\Theta(1 - x - \delta)$ part of (6.34). The lengthy finite contributions can be found in our computer program, which is available upon request. Our unpolarized results agree with those of [45].

We can quickly derive the soft limits of the $\tilde{\sigma}_{\text{QED}}$ and $\tilde{\sigma}_{\text{OK}}$, as we did in the case of $\tilde{\gamma}g$ in (7.21) and (7.22)

\[
\tilde{S}_{\text{QED}} = \frac{8}{s^2} \left[ \frac{s}{t \, \bar{u}'} + \frac{2t_1}{s_3 t'} - 2u_1 - \frac{2u_1}{s_3 t'} + \frac{s - 2m^2}{s_3} - \frac{m^2 - m^2}{s_3} \right] \tilde{A}_{\text{QED}} ,
\]

\[
\tilde{S}_{\text{OK}} = \frac{8}{s^2} \left[ \frac{s}{t \, \bar{u}'} + \frac{t_1}{s_3 t'} - \frac{t_1}{\bar{u}'} + \frac{2u_1}{s_3 t'} - \frac{s - 2m^2}{s_3} \right] \tilde{A}_{\text{QED}} ,
\]
in agreement with [45] in the unpolarized case. From them we derive the soft cross section, as for (7.23) and (7.24):

$$\left( \frac{d^2 \tilde{\sigma}_{qq}^{(1)}_{\text{QED}}}{dt_1 du_1} \right)^s = \frac{C_F}{4N_C} 2C_F F_\gamma G_\gamma \alpha_s^3 \tilde{A}_{\text{QED}} \left\{ \frac{8}{\varepsilon^2} - \frac{4}{\varepsilon} \ln \frac{sm^2}{t_1 u_1} + \frac{16}{\varepsilon} \ln \frac{t_1}{u_1} + 2 
- 8 \ln \frac{t_1}{u_1} + \ln \frac{sm^2}{t_1 u_1} + 2 \text{Li}_2 \left( 1 - \frac{sm^2}{t_1 u_1} \right) + 8 \text{Li}_2 \left( 1 - \frac{t_1}{u_1} \right) \right\} \delta(s_4), \quad (7.47)$$

$$\left( \frac{d^2 \tilde{\sigma}_{qq}^{(1)}_{\text{QED}}}{dt_1 du_1} \right)^P = \frac{C_F}{4N_C} C_A F_\gamma G_\gamma \alpha_s^3 \tilde{A}_{\text{QED}} \left\{ - \frac{4}{\varepsilon} \ln \frac{sm^2}{t_1 u_1} - \frac{12}{\varepsilon} \ln \frac{t_1}{u_1} - \ln \frac{sm^2}{t_1 u_1} + 6 \ln \frac{t_1}{u_1} + \ln \frac{t_1}{u_1} \right\} \delta(s_4), \quad (7.48)$$

where $S(\varepsilon)$ and $G_\gamma$ are defined in (7.25) and (7.26), respectively. $\tilde{A}_{\text{QED}}$ is the LO expression of (2.30). Our unpolarized results for the soft bremsstrahlung cross section once more are identical to those of [45].

We now perform mass factorization for the hard $H$ and the renormalized virtual plus soft $V + S$ part, keeping in mind to use (6.35) to guarantee helicity conservation. We can then split the $V + S$ part as

$$\left( \frac{d^2 \tilde{\sigma}_{qq}^{(1)}}{dt_1 du_1} \right)^{V+S} = \frac{\alpha_s^3}{s^2} \frac{C_F}{4N_C} \left[ 2C_F \left( \tilde{K}_{\text{QED}} + \tilde{K}_{\text{QED}}^\Delta \right) + C_A \left( \tilde{K}_{\text{OK}} + \tilde{K}_{\text{OK}}^\Delta \right) \right] + \delta(s_4), \quad (7.49)$$

where we have included the virtual quark loop contribution of (7.39) in the $\tilde{K}_{\text{QED}}$ and explicitly separated out the part proportional to $\beta_0$, which corresponds to (7.8) and vanishes for $\mu_r = \mu_f$. The coefficients are given in App. C and are exactly equal in the unpolarized case to those found in App. A of [45]. Actually we show in App. C the unpolarized results, which then can be directly compared to the results of [45]. We find for our polarized results that as expected helicity conservation holds and thus the polarized coefficients are simply (-1) times the unpolarized ones\(^7\). We find that helicity conservation holds for the hard part as well after mass factorization. Thus our unpolarized and polarized $H$ parts

\[^7\text{Helicity conservation requires for a quark-antiquark quark vertex that } |M|^2(++) = 0 \text{ and hence that } |M|^2 = -\Delta |M|^2, \text{ see (2.10) and (2.11).}\]
are equal to those of [45], with a sign for the polarized case. It is important to keep in mind though, that this would not have happened, if we had not corrected the helicity breaking of the HVBM $\gamma_5$ scheme [54] by using (6.35). Furthermore we would also not have obtained this result without calculating the hat momenta contributions, which happen to be equal to one half the HVBM corrections.

We can of course again extract scaling functions from our results according to (7.2). Note that we enforce (7.8), i.e., the only dependence on the renormalization scale apart from $\alpha_s(\mu_r^2)$ is due to a logarithm $\ln(\mu_r^2/\mu_f^2)$. So $\ln(\mu_r^2/m^2)$ terms from $\tilde{K}_{OK}$ and $\tilde{K}_{QL}$ are changed to $\ln(\mu_f^2/m^2)$ and the additional $\tilde{K}_{RF}$ collects the $\ln(\mu_r^2/\mu_f^2)$ pieces to keep the sum unchanged. This means $\tilde{f}_{q\bar{q}}^{(1)}$ multiplying $\ln(\mu_f^2/m^2)$ receives additional contributions when requiring (7.8). We plot the polarized scaling functions in Fig. 7.14. Apart from extending the $\eta$-range and having a sign due to helicity conservation, this plot does not exactly reproduce Fig. 5 of [45], though the differences, which occur in the medium $\eta$ range, are small. The reason is that when one includes the quark loop contributions

Figure 7.14: The polarized quark-antiquark scaling functions in LO $\Delta f_{q\bar{q}}^{(0)}$, and NLO $\Delta f_{q\bar{q}}^{(1)}$ and $\Delta f_{q\bar{q}}^{(2)}$, in the $\overline{\text{MS}}$ scheme as function of $\eta$. The quark loop contribution is included with the number of light flavors $n_{lf} = 3$. For comparison the effective NLO combination $\Delta f_{q\bar{q}}^{(0)} + 2.7 \Delta f_{q\bar{q}}^{(1)}$ is also shown.
7.3. Gluon-(Anti)Quark and Quark-Antiquark Scaling Functions

![Graph](image)

Figure 7.15: The non-abelian (OK), abelian (QED), and quark loop (QL) parts of the NLO polarized scaling function $\Delta f_{q\bar{q}}^{(1)}$ in the $\overline{\text{MS}}$ scheme as function of $\eta$. The quark loop contribution is shown for three and four light flavors $n_f$, and the OK and QED scaling functions have been divided by six. OK+QED+QL($n_f=3$) will give the $\Delta f_{q\bar{q}}^{(1)}$ of Fig. 7.14.

$\tilde{K}_{QL}$, one has to specify the number of light flavors $n_f$. We have chosen $n_f = 3$ with charm production in mind, whereas the authors of [45] have chosen $n_f = 4$. Thus there are slight differences in the soft plus virtual parts, which disappear when we also set $n_f = 4$. We have again plotted the “effective” NLO combination for charm production $\Delta f_{q\bar{q}}^{(0)} + 2.7 \Delta f_{q\bar{q}}^{(1)}$, which gives an estimate of the total scaling function at NLO with $4\pi \alpha_s(m_c^2) \simeq 2.7$. We see that the NLO contributions strongly dominate towards threshold $\eta \to 0$. Again this comes about on one hand because of a Coulomb singularity yielding a constant at threshold in the $S + V$ part, see Fig. 7.12 (d), and on the other hand because of soft gluon emission left-overs in the hard part, see Fig. 7.13. There are no flavor excitation graphs in this process, so we do not find an enhancement at $\eta \to \infty$. Note that the NLO part $\Delta f_{q\bar{q}}^{(1)}$ changes sign in the $\eta$ range of approximately 0.7 to 20. Thus the effective NLO combination (dotted line) is above the LO result (dashed line) in that region. Concerning hadronic cross sections at RHIC [32] with $\sqrt{s} = 200$ GeV and $m_c = 1.5$ GeV, we find $x_{\text{min}} = 2.25 \cdot 10^{-4}$. So using (7.29) we get for the product $x_1 x_2$, 

-0.015
-0.01
-0.005
0
0.005
0.01
0.015
-0.02

$\eta = s/(4 \text{ m}^2) - 1$
which replaces the single $x$ of photoproduction, $3.8 \times 10^{-4}$ to $4.5 \times 10^{-3}$ in this $\eta$ range. Thus we can expect significant contributions from this region.

Finally, in Fig. 7.15 we show $\Delta f_{\eta}^{(1)}$ split according to its color-structure. The sum of the non-abelian, abelian and quark loop contributions gives back $\Delta f_{\eta}^{(1)}$, see (7.41) and (7.49). To make the small quark loop parts more visible, we have divided the other contributions by a factor six in the plot. We see once more the strong cancellations between the "OK" and "QED" parts. But even their sum dominates over the "QL" contribution for $\eta \lesssim 0.4$, there the ratio "QL/(OK+QED)" is below 10%. At threshold we find $\Delta f_{\eta}^{(1)} = \frac{C_F}{4N_C}(2C_F - C_A)\pi$. The "QL" part is shown for three and four light flavors and we see that the changes introduced by adding one light flavor are small, and will mainly be felt in the medium $\eta$ range. Finally we would like to mention that we can again obtain the results for the production of a heavy quark instead of a heavy antiquark by switching $p_1 \leftrightarrow p_2$. In this case it is however easier to use charge conjugation

$$\frac{d^8\hat{\sigma}}{dt_{1} du_{1}}(q\bar{q} \rightarrow \overline{Q}) = \frac{d^8\hat{\sigma}}{dt_{1} du_{1}}(\bar{q}q \rightarrow Q) \quad \text{and} \quad \frac{d^8\hat{\sigma}}{dt_{1} du_{1}}(q\bar{q} \rightarrow Q) = \frac{d^8\hat{\sigma}}{dt_{1} du_{1}}(\bar{q}q \rightarrow \overline{Q}) \quad \text{(7.50)}$$

and additionally $k_1 \leftrightarrow k_2$ or equivalently $t_1 \leftrightarrow u_1$, which crosses the initial states $q\bar{q} \leftrightarrow \bar{q}q$. So in this case one obtains the corresponding heavy quark production expressions by interchanging $t_1 \leftrightarrow u_1$, with $t_1$ and $u_1$ now referring to the heavy quark $[45]$. Naturally we can also derive the results for a light antiquark instead of a light quark as parton for one hadron and vice versa for the other hadron by using $k_1 \leftrightarrow k_2$ ($t_1 \leftrightarrow u_1$) $[45]$.

### 7.4 Gluon-Gluon Scaling Functions

The final subprocesses we have to calculate for hadroproduction are the NLO corrections to gluon-gluon fusion

$$\hat{g}^a(k_1) + \hat{g}^b(k_2) \rightarrow Q_i(p_1) + \overline{Q}_j(p_2) \quad \text{(7.51)}$$

The virtual corrections, with the same external momentum and color assignment as in LO (7.51), are computed with the $2 \rightarrow 2$ phase space (2.24), and are displayed in Fig. 7.16. We can again split the squared matrix element according to color factors

$$|\hat{M}_{V}^{2B}| = 2\text{Re} \left( \hat{M}_{V}^{2B} \hat{M}_{\overline{B}}^{2} \right) = E_{z}^{2} g_{\hat{E}} g_{\hat{F}} \frac{1}{2(N_{C}^{2} - 1)} \left[ (2C_{F})^{2}\hat{U}_{QED} + C_{A}^{2}\hat{U}_{QED} + \hat{U}_{KQ} + C_{A}\hat{U}_{QG} \right] \quad \text{(7.52)}$$

where the "abelian" $\hat{U}_{QED}$ is connected to $\hat{V}_{QED}$ of (7.15) with the usual factor $1/(2N_{C})$ for replacing a photon by a gluon. $\hat{U}_{QG}$ only receives contributions from the quark loops. The other two collect "non-abelian" contributions. Compared to Eq. (3.3) in $[44]$, we have averaged over color and chosen a slightly different way of splitting the results according
Figure 7.16: The NLO virtual corrections to $\bar{q}q \rightarrow Q\bar{Q}$. Additional graphs are obtained by: replacing the photon by a gluon in Fig 7.3; reversing the heavy quark lines in (a), (d), and (e); and setting the loop particle to a (heavy) quark and ghost in (h), a ghost in (j) and a heavy quark in (k). Massless particle loops similar to graph (e), (n) and (o) vanish, see (3.3).
to color. Also we already include a factor 1/4 for spin-averaging in the unpolarized and as a convention in the polarized case. Taking all this into account, for comparisons with [44] one should use

\[
U_{\text{QED}} = \frac{1}{2} V_{\text{QED}}^{\text{BKNS}}, \quad U_{\text{OQ}} = \frac{1}{2} (V_{\text{O}}^{\text{BKNS}} - V_{\text{QED}}^{\text{BKNS}}), \quad U_{\text{KL}} = \frac{1}{2} V_{\text{L}}^{\text{BKNS}},
\]

(7.53)

where the coefficients marked “BKNS” are those of [44]. Note that due to our “ghost trick”, see Fig. 2.1 and App. B.4, for the diagram structures (a), (f), (g), (h), (j), (l) and (m) in Fig. 7.16, there are also diagrams with incoming ghosts to be considered, which are not shown. We postpone further discussion of the virtual results, and examine first the bremsstrahlung reactions.

![Feynman diagrams](image)

Figure 7.17: Feynman diagrams for the NLO gluon bremsstrahlung process $g\gamma \rightarrow Q\bar{Q}g$. Replacing the photon by a gluon in Fig. 7.4 and reversing the heavy quark lines of (a) yields the remaining graphs. Many initial to final or initial to initial ghost contributions, for example (h) and (i), have to be subtracted in the unpolarized case to cancel unphysical polarization contributions, compare Fig. 2.1 and App. B.4.
7.4. Gluon-Gluon Scaling Functions

The bremsstrahlung diagrams are presented in Fig. 7.17 and we assign color and momentum according to

\[ g^a(k_1) + g^b(k_2) \rightarrow Q_i(p_1) + \overline{Q}_j(p_2) + g^f(k_3). \]  

(7.54)

Note that we have this time external ghost graphs both for replacing two initial gluons and for replacing one initial and one final state gluon. There is a similar color split for the squared matrix element

\[ |\tilde{M}_R|^2 = \frac{1}{2(N_c^2 - 1)} \left( (2C_F)^2 \tilde{D}_{QED} + C_A^2 \tilde{D}_{OQ} + \tilde{D}_{QG} \right), \]

(7.55)

and compared to the \( R_s \) in Eq. (4.4) of [44] analogous relations as in (7.53) apply. The collinear pole part of the hard gluon-gluon cross section then becomes

\[
\left( \frac{d^2\sigma^{(1)}_{gg,0Q}}{dt_1,du_1} \right)^H = \frac{C_A^2}{2(N_c^2 - 1)} F_2^g G_1^H \nu^2 \alpha_s^2 \varepsilon \left[ (1 - H_{L1}) \tilde{H}_{0K1}^{pole} + (1 - H_{L2}) \tilde{H}_{0K2}^{pole} \right] + O(1),
\]

(7.56)

\[
\left( \frac{d^2\sigma^{(1)}_{gg,KQ}}{dt_1,du_1} \right)^H = -\frac{1}{2(N_c^2 - 1)} F_2^g G_1^H \nu^2 \alpha_s^2 \varepsilon \left[ \tilde{H}_{0K1}^{pole} + \tilde{H}_{0K2}^{pole} \right] + O(1),
\]

(7.57)

\[ H_{L1} = \frac{2t_1(x_1u_1)}{(x_1s)^2}, \quad H_{L2} = \frac{2(x_2t_1)u_1}{(x_2s)^2}, \]

(7.58)

\[ H_{0K1}^{pole} = \frac{1}{t_1} \left[ \frac{1}{1 - x_1} + \frac{1}{x_1} - 2 - x_1(1 - x_1) \right], \]

(7.59)

\[ \Delta H_{0K1}^{pole} = \frac{1}{t_1} \left( \frac{1}{1 - x_1} - 2x_1 + 1 \right) \left( \frac{x_1u_1}{x_1u_1} + \frac{4m^2(x_1s)}{t_1(x_1u_1)} \right) \left[ 2m^2(x_1s) - 1 \right], \]

\[ H_{0K2}^{pole} = \frac{1}{u_1} \left[ \frac{1}{1 - x_2} + \frac{1}{x_2} - 2 - x_2(1 - x_2) \right], \]

(7.60)

\[ \Delta H_{0K2}^{pole} = \frac{1}{u_1} \left( \frac{1}{1 - x_2} - 2x_2 + 1 \right) \left( \frac{x_2t_1}{x_2t_1} + \frac{4m^2(x_2s)}{(x_2t_1)u_1} \right) \left[ 2m^2(x_2s) - 1 \right], \]

and the “QED” part is completely finite. \( G_1^H \) is defined in (6.5) and \( x_1, x_2 \) in (6.4). We have written the results in a form which is easily comparable with the mass factorization formula (6.30). To this end note that \( 2C_F C_A = C_A^2 - 1 \). Our unpolarized results agree\(^8\)

\(^8\)The comparison is somewhat protracted, since they do not bring the result in a simple “factorization” form. Replacing \( s + t_1 \rightarrow -u_1/x_2 \) in their expressions helps to disentangle the terms.
with those of [44]. The finite results are too long to be quoted here, but can be found in
our computer program.
We take the soft limit of the matrix elements in (7.55) and find

\[
\tilde{S}_{\text{QED}} = -\frac{2}{s_4} \left[ m^2 + \frac{m^2}{s_3} + \frac{2m^2 - s}{s_3} \right] \tilde{B}_{\text{QED}},
\]
\[
\tilde{S}_{\text{QG}} = \frac{2}{s_3^2} \left[ \frac{2m^2 - s}{s_3} + \left( \alpha_s^2 + \frac{2m^2 t_1 u_1}{s^2} \right)^2 \left( 1 + \frac{1}{s_3^2} \right) + \frac{t_1^2 u_1}{s^2} \left( \frac{1}{\nu} + \frac{1}{s_3^2} \right) \right] \tilde{B}_{\text{QED}},
\]
\[
\tilde{S}_{\text{QK}} = -\frac{2}{s_4^2} \left[ \left( \alpha_s^2 + \frac{2m^2 - s}{s_3} \right) \left( 1 + \frac{t_1 u_1}{s^2} \right) + \frac{2m^2 t_1 u_1}{s^2} \left( 1 + \frac{1}{s_3^2} \right) + t_1 \left( \frac{1}{\nu} + \frac{1}{s_3^2} \right) \right] \tilde{B}_{\text{QED}}.
\]

Using relations analogous to (7.53), we find that these limits are indeed equal to those
found in [44] for the unpolarized case.

From these soft matrix elements we can directly derive the soft cross sections as before, and obtain

\[
\left( \frac{d^2\tilde{\sigma}^{(1)}_{gg,\text{QED}}}{dt_1 du_1} \right)^S = \frac{(2\pi)^2}{2(N_C^2 - 1)} F_G^2 G^2 E^2 \alpha_s^3 \tilde{B}_{\text{QED}} \left\{ -\frac{2}{\varepsilon} + 1 + \frac{2m^2 - s}{s_\beta} \left[ \ln \varkappa - S(\varkappa) \right] \right\} \delta(s_4),
\]
\[
\left( \frac{d^2\tilde{\sigma}^{(1)}_{gg,\text{QG}}}{dt_1 du_1} \right)^S = \frac{C_A^2}{2(N_C^2 - 1)} F_G^2 G^2 E^2 \alpha_s^3 \tilde{B}_{\text{QED}} \left\{ \frac{2t_1 u_1}{s_\beta} \left( \frac{2}{\varepsilon} - 1 \right) + \left( 1 - \frac{2t_1 u_1}{s_\beta} \right) \right\}
\cdot \left[ \frac{8}{\varepsilon^2} + \frac{2}{\varepsilon} \ln \frac{m^2}{t_1 u_1} + \frac{1}{2} \left( \ln^2 \frac{m^2}{t_1 u_1} + \ln \frac{t_1}{u_1} - \ln^2 \varkappa \right) + \text{Li}_2 \left( 1 - \frac{m^2}{t_1 u_1} \right) \right]
\cdot \left[ \ln \frac{t_1}{u_1} + \frac{2}{\varepsilon} \ln \varkappa \right] - \text{Li}_2 \left( 1 + \frac{t_1}{u_1} \varkappa \right) + \text{Li}_2 \left( 1 - \frac{u_1}{t_1 \varkappa} \right)
- \frac{2m^2 - s}{s_\beta} \left[ \frac{2t_1 u_1}{s_\beta} \ln \varkappa - S(\varkappa) \right] \right\} \delta(s_4),
\]
\[
\left( \frac{d^2\tilde{\sigma}^{(1)}_{gg,\text{QK}}}{dt_1 du_1} \right)^S = \frac{C_A^2}{2(N_C^2 - 1)} F_G^2 G^2 E^2 \alpha_s^3 \tilde{B}_{\text{QED}} \left\{ -\frac{8}{\varepsilon^2} - \frac{2t_1 u_1}{s_\beta} \left( \frac{2}{\varepsilon} - 1 \right) - \ln^2 \frac{t_1}{u_1}
+ \ln \varkappa - \frac{2(m^2 - s)}{s_\beta} \left[ -\frac{t_1 u_1}{s_\beta} \ln \varkappa + \left( 1 + \frac{t_1 u_1}{s_\beta} \right) S(\varkappa) \right] \right\} \delta(s_4),
\]
where $S(\infty)$ and $G_5^2$ are defined in (7.25) and (7.26), respectively. Our unpolarized results agree\(^9\) with those of [44]. We see comparing (7.61) and (7.64) with (7.21) and (7.23), that the “QED” part of the gluon-gluon partonic cross section is indeed just $1/(2N_C)$ of the “QED” part of the photon-gluon one. So our choice is “natural” concerning the color-factor of the “QED” part, since we get the usual factor for replacing a photon by a gluon.

\[ \eta = s/(4 m^2 - 1) \]

Figure 7.18: The hard ($H + \Delta$) part of the NLO polarized and unpolarized scaling functions $\Delta f_{gg}^{(1)}$ and $f_{gg}^{(1)}$, respectively, in the $\overline{\text{MS}}$ scheme as function of $\eta$. For comparison the LO polarized and unpolarized scaling functions $\Delta f_{gg}^{(0)}$ and $f_{gg}^{(0)}$, respectively, are also shown.

Now we should combine the virtual and soft cross sections. However, though the matrix elements and tensor integrals have been calculated, we have not yet combined the virtual results. This will be done in a later publication. For the time being we will just take the $\ln(\Delta/m^2)$ parts of the soft cross sections (7.64) to (7.66) and add them to the reduced hard parts after mass factorization. This way we can already present the “hard” part of the $f_{gg}^{(1)}$ coefficient functions in Fig. 7.18. There the solid line shows the “hard” part of the polarized scaling function $\Delta f_{gg}^{(1)}$, and the dot-dashed line displays

\(^9\)It is useful to note that their color-factor $K \bar{C}_\text{QED} = 2[(2C_F)^2 - C_A^2 + 3]/[2(N_C^2 - 1)]$. 

the corresponding unpolarized scaling function \( f_{gg}^{(1)} \). For comparison we also plot the dashed and dotted curves, displaying the polarized \( \Delta f_{gg}^{(0)} \) and unpolarized \( f_{gg}^{(0)} \) LO scaling functions, respectively. We see that the situation is very similar to the \( \gamma g \) case concerning the threshold and high energy limits. But here the NLO corrections are even larger, in particular at high energies. The corresponding heavy quark production expressions have the same form, but with \( t_1 \) and \( u_1 \) referring to the heavy quark, since the squared matrix elements are \( p_1 \leftrightarrow p_2 \) symmetric [43]. We postpone further discussions of the \( gg \) scaling functions till the time when the virtual plus soft part and hence the complete result is available.
Chapter 8

Hadron Level Results

8.1 Hadronic Cross Sections

Let us first of all recall the relevant formulae for calculating differential single-inclusive heavy (anti)quark distributions. We denote the momenta in the heavy (anti)quark production cross section of a hadron of type $a$ with a hadron of type $b$ by

$$H^a(K_1) + H^b(K_2) \rightarrow \overline{Q}(p_2) [Q(p_1)] + X,$$

and use the following hadronic invariants for the observed heavy anti-quark

$$S \equiv (K_1 + K_2)^2 \quad \text{with} \quad s = (x_1 K_1 + x_2 K_2)^2 = x_1 x_2 S,$$

$$T_1 \equiv (K_2 - p_2)^2 - m^2 \quad \text{with} \quad t_1 = (x_2 K_2 - p_2)^2 - m^2 = x_2 T_1,$$

$$U_1 \equiv (K_1 - p_1)^2 - m^2 \quad \text{with} \quad u_1 = (x_1 K_1 - p_1)^2 - m^2 = x_1 U_1,$$

where we have introduced the momentum fractions $x_1$ in $k_1 = x_1 K_1$ and $x_2$ in $k_2 = x_2 K_2$ to relate the hadronic to the partonic variables in (2.18), thus $K_1^2 = K_2^2 = 0$. For an observed heavy quark one would set $p_1 \rightarrow p_2$ in (8.2). Thus the hadronic and partonic Mandelstam variables are always defined with respect to the observed heavy (anti)quark. How one can obtain the reduced partonic cross sections for heavy quark instead of heavy antiquark production has been discussed for each subprocess individually in Chap. 7.

We have in the hadronic cross section formula (6.21) the conditions $0 \leq x_1, x_2 \leq 1$. But we know that

$$s_4 = s + t_1 + u_1 = x_1 x_2 S + x_1 T_1 + x_2 U_1 \geq \Delta,$$

where $\Delta > 0$ only for the “hard” parts and zero otherwise. Hence we can derive lower limits from the process kinematics

$$\frac{d\sigma^{ab}(K_1, K_2)}{dT_1 dU_1} = \sum_{l,m} \int_{x_1}^{1} dx_1 \int_{x_2}^{1} dx_2 x_1 f_l^a(x_1, \mu_1^2) x_2 f_m^b(x_2, \mu_2^2) \frac{d\hat{\sigma}_{lm}(x_1 K_1, x_2 K_2)}{dt_1 du_1},$$

(8.4)
with
\[ x_{1 \text{ min}} = -\frac{T_1}{S + U_1}, \quad \text{and} \quad x_{2 \text{ min}} = \frac{\Delta - x_1 U_1}{x_1 S + T_1}, \quad (8.5) \]
and \( \Delta = 0 \) in (8.5) except for the “hard” parts of the cross section\(^1\). Note that the extra factor \( x_1 x_2 \) on the r.h.s. in comparison to (6.21) comes from \( dt_1 du_1 = x_1 x_2 dT_1 dU_1 \). For the hard \( 2 \rightarrow 3 \) processes (Born, virtual and soft ones) have a factor \( \delta(s + t_1 + u_1) = \delta(x_1 x_2 S + x_2 T_1 + x_1 U_1) \), so then (8.4) becomes
\[ \frac{d\bar{\sigma}^{ab}(K_1, K_2)}{dT_1 dU_1} = \sum_{l,m} \int_{x_{1 \text{ min}}}^{1} \frac{dx_1}{x_1 S + T_1} x_1 \tilde{f}_l^a(x_1, \mu_f^2) x_2 \min \tilde{f}_m^b(x_2, \mu_f^2) \frac{d\bar{\sigma}^{2-3}_{lm}(x_1 K_1, x_2 K_2)}{dt_1 du_1}, \quad (8.6) \]
with \( \Delta = 0 \) in \( x_{2 \text{ min}} \). For the hard \( 2 \rightarrow 3 \) parts it is advantageous to change the inner integration variable \( x_2 \rightarrow s_4 \), then we have
\[ \frac{d\bar{\sigma}^{ab}(K_1, K_2)}{dT_1 dU_1} = \sum_{l,m} \int_{x_{1 \text{ min}}}^{1} \frac{dx_1}{x_1 S + T_1} x_1 \tilde{f}_l^a(x_1, \mu_f^2) \int_{\Delta}^{s_{4 \text{ max}}} ds_4 \int_{x_2 \min}^{1} \tilde{f}_m^b(x_2', \mu_f^2) \frac{d\bar{\sigma}^{2-3}_{lm}(x_1 K_1, x_2' K_2)}{dt_1 du_1}, \quad (8.7) \]
with
\[ x_2' = \frac{s_4 - x_1 U_1}{x_1 S + T_1} \quad \text{and} \quad s_{4 \text{ max}} = x_1 S + T_1 + x_1 U_1. \quad (8.8) \]
Note the common factor \( 1/(x_1 S + T_1) \) in (8.6) and (8.7). Written this way, it is obvious that (8.6) is the \( s_4 \rightarrow 0 \) limit of (8.7). Also we can easily see how \( 2 \rightarrow 2 \) processes can be included in the \( 2 \rightarrow 3 \) integration of (8.7) by using (5.67) for the partonic cross sections and \( x_2 \rightarrow x_{2 \text{ min}}(\Delta = 0) \) in \( \tilde{f}_m^b(x_2', \mu_f^2) \).

To obtain the integration limits for the total hadronic cross section, we can proceed like for the derivation of the limits for the partonic cross sections, see the discussion leading to (7.2). We just have to replace the \( s, t_1, u_1 \) by their hadronic counterparts \( S, T_1, U_1 \) and so the result is
\[ \tilde{\sigma}^{ab}(S, m^2) = \int_{\tilde{f}_l^{a(1-\beta_g)}}^{T_1 + \beta_g} d(-T_1) \int_{\tilde{f}_m^{b(1-\beta_g)}}^{S + T_1} d(-U_1) \frac{d\bar{\sigma}^{a b}(S, T_1, U_1)}{dT_1 dU_1} \quad (8.9) \]
\[ = \sum_{l,m} \int_{x_{1 \text{ min}}}^{1} dx_1 \int_{x_{2 \text{ min}}}^{1} dx_2 \int_{\Delta}^{s_{4 \text{ max}}} ds_4 \tilde{f}_l^a(x_1, \mu_f^2) \tilde{f}_m^b(x_2, \mu_f^2) \frac{d\bar{\sigma}^{2-3}_{lm}(x_1 x_2 S, m^2)}{dt_1 du_1}, \]
\(^1\)The tilde notation refers here, as throughout the text, to both the polarized case, \( \tilde{a} \rightarrow \Delta a \), and the unpolarized case, \( \tilde{a} \rightarrow a \).
\[ \beta_s = \sqrt{1 - \frac{4m^2}{S}}, \quad x_{\min} = \frac{4m^2}{S} = 1 - \beta_s^2, \quad (8.10) \]

where the \( \hat{\sigma}_{\text{tm}} \) are the total partonic cross section of (7.2). The second line of (8.9) follows from inserting (8.4) and reshuffling the integrations. In the case of “direct” photoproduction we can insert

\[ f'(x_1, \mu^2_f) = \delta(1 - x_1), \quad (8.11) \]

in the formulae (8.4) to (8.9) we have just derived, see the discussion leading to (6.26), which immediately yields simpler formulae by collapsing the \( x_1 \)-integration to \( x_1 = 1 \).

The differential heavy (anti)quark cross section (8.4) should be expressed in variables more suited for experimental measurements:

\[
\begin{align*}
\text{transverse momentum/mass:} & \quad x_T \equiv \frac{p_T}{p_T^{\text{max}}}, \quad m_T^2 \equiv m^2 + p_T^{2\text{hCMS}} = \frac{T_1U_1}{S}, \\
\text{rapidity:} & \quad y \equiv \text{artanh} \frac{p_L}{E}^{\text{hCMS}} = \frac{1}{2} \ln \frac{U_1}{T_1}, \\
\text{Feynman - x:} & \quad x_F \equiv \frac{p_L}{p_L^{\text{max}}}^{\text{hCMS}} = \frac{1}{\beta_s} \frac{T_1 - U_1}{S},
\end{align*}
\]

(8.12)

where the relations to invariant hadronic Mandelstam variables (8.2) are valid in the hadronic center of mass system (hCMS). The energy and the longitudinal momentum of the heavy antiquark are given by \( E = m_T \cosh y \) and \( p_L = m_T \sinh y \), respectively. \( p_T = |\vec{p}_T| \) is the absolute size of the transverse moment and

\[ p_T^{\text{max}} = p_L^{\text{max}} = \frac{\sqrt{S} \beta_s}{2}. \quad (8.13) \]

\( y \) and \( x_F \) of the observed \( \bar{Q} \) in (8.12) are defined in the hCMS with the forward direction \( (y, x_F > 0) \) along the incoming particle with \( K \) (the photon in photoproduction), i.e.,

\[
\begin{align*}
T_1 & = -\sqrt{S}m_T e^{-y} = -\sqrt{S}p_L^{\text{max}}(\chi - x_F), \\
U_1 & = -\sqrt{S}m_T e^y = -\sqrt{S}p_L^{\text{max}}(\chi + x_F),
\end{align*}
\]

(8.14)

where \( \chi \equiv \sqrt{x_F^2 + (m_T/p_L^{\text{max}})^2} \). Under a boost in the direction of the unit vector \( \vec{e}_L \) with \( p_L = \vec{p} \cdot \vec{e}_L \) to a frame \( K' \) with velocity \( \beta' \), \( p'_T = p_T \) is of course invariant and \( y' = y - \text{artanh} \beta' \). Hence also the shape of a rapidity distribution \( df(y')/dy' = df(y)/dy \) remains unchanged by such a boost.

The Jacobians needed to express (8.4) in the variables (8.12) are

\[ dT_1 dU_1 = S dm_T^2 dy = \frac{S}{\chi} dm_T^2 dx_F, \quad (8.15) \]
and \( dm_T^2 = 2x_T(p_T^\text{max})^2 dx_T \), etc. By integrating the variables in (8.12) over the appropriate limits

\[
S \int_{m^2}^{S/4} dm_T^2 \int_{-\arccosh\left(\frac{\sqrt{s}}{2m_T}\right)}^{\arccosh\left(\frac{\sqrt{s}}{2m_T}\right)} dy = S \int_{-\frac{1}{2} \ln \frac{1 + \beta}{1 - \beta}}^{\frac{1}{2} \ln \frac{1 + \beta}{1 - \beta}} dy \int_{m^2}^{\frac{s}{4 \cosh^2 y}} dm_T^2, \tag{8.16}
\]

\[
S \int_{m^2}^{S/4} dm_T^2 \int_{-\pi}^{\pi} \frac{1}{\sqrt{1 - \frac{4m_T^2}{s}}} dx_F = S \int_{-1}^{1} dx_F \int_{m^2}^{\frac{s}{(1 - \beta^2 x_F^2)}} \frac{dm_T^2}{\lambda}, \tag{8.17}
\]

the total cross section (8.9) is of course recovered.

Finally it should be noted that experiments do not determine the (differential) longitudinally polarized cross section \((d) \Delta \sigma\) itself, but rather the corresponding spin asymmetry

\[
A^{ab} = \frac{(d) \Delta \sigma^{ab}}{(d) \sigma^{ab}}. \tag{8.18}
\]

In (8.18), which is nothing but the counting rate asymmetry for the two possible helicity alignments of the incoming hadrons (2.2), the experimental normalization uncertainty and some systematical errors conveniently drop out. However, in the following we will concentrate on the polarized cross section itself as well, since we are interested in the influence of the spin-dependent NLO corrections. The calculation of the spin asymmetry (8.18) introduces additional theoretical uncertainties associated with the unpolarized (differential) cross section.

### 8.2 Numerical Studies for Photoproduction

Equipped with the necessary technical framework, we now turn to some numerical applications. Unless otherwise stated we use here the GRV’94 [62] and GRSV standard [15] set of unpolarized and longitudinally polarized parton distributions, respectively. However, it should be mentioned that the detailed choices with respect to the running of \( \alpha_s \) and the evolution of the parton distributions used in the \( \overline{\text{MS}} \) parton density fits are usually not exactly the same as in our \( \overline{\text{MS}}_m \) scheme. Generally \( n_f \) instead of \( n_{lf} \) is used in \( \beta_{0,1} \), i.e., the produced heavy quark flavor is not explicitly decoupled at low energies. Furthermore, bottom production in the \( \overline{\text{MS}}_m \) scheme requires four light flavors, i.e., charm is treated as “massless” and should enter the calculation with its own evolving probability distribution. But for example in the case of GRV/GRSV [62, 15], flavor thresholds are only introduced in the running of \( \alpha_s \), i.e., there is no charm distribution. On the other hand, the effect of setting \( n_{lf} \to n_f \) on the running of \( \alpha_s \) is negligible. Also the quark contribution is small compared to the gluon one, as we will see, but particularly so for “heavy” (massless) quarks, which are introduced only at high scales and are always suppressed due to the longer evolution length of the light partons. Hence we will simply use \( n_f \) instead of \( n_{lf} \) in \( \beta_{0,1} \) for the running of \( \alpha_s \) and use only three light flavors even when
calculating bottom production. So our conventions for calculating hadronic cross sections match those of the GRV/GRSV parton densities [62, 15], but we nevertheless use our \( \overline{M}_m \) results for the reduced partonic cross sections. The errors introduced by this slight inconsistency are completely swamped by the scale variation uncertainties we will discuss next and hence are of no practical relevance. Since only the photoproduction result is complete in NLO, we can only examine this reaction\(^2\). Unfortunately we have no data so far, but in the near future COMPASS [31] is going to measure the total (anti)charm spin asymmetry \( A_{\chi}^{p} \) with sufficient accuracy. Therefore we mainly focus on the kinematical range accessible by COMPASS in our analysis below, i.e., \( \sqrt{S} = \sqrt{S_{\gamma p}} = 10 \text{ GeV} \). It is currently under scrutiny whether it is physically feasible and sensible to run HERA in a polarized collider mode in the future [28], and therefore we either show or comment on the corresponding results at HERA collider energies as well. At HERA a sizable portion of the \( ep \) c.m. energy 300 GeV can be transferred to the photon-proton system. We use \( \sqrt{S_{\gamma p}} \simeq 200 \text{ GeV} \) in the following as typical\(^3\) HERA photoproduction energy.

In order to investigate the theoretical uncertainty of predictions for the total polarized cross section induced by the dependence on \( \mu_r, \mu_f \) and \( m_c \), we define

\[
R(r, f, c) = \frac{\Delta \sigma_{\gamma p}^c(r, f, c) - \Delta \sigma_{\gamma p}^c(r = 2.5, c = 1.5)}{\Delta \sigma_{\gamma p}^c(r = 2.5, c = 1.5)}
\]

\[
\mu_r^2 = r m_c^2, \quad \mu_f^2 = f m_c^2, \quad m_c = c \text{ GeV},
\]

which uses the prediction for one particular choice of scales \( \Delta \sigma_{\gamma p}^c(\mu_r^2 = \mu_f^2 = 2.5 m_c^2, m_c = 1.5 \text{ GeV}) \) as basic value for computing relative deviations. In the plots of \( R \) the LO and NLO GRSV standard parton densities [15] have been used. We start by keeping \( m_c = 1.5 \text{ GeV} \) fixed and varying only \( \mu_r \) and \( \mu_f \). Thus we plot \( R(r, f, 1.5) \) in Fig. 8.1 for two center of mass energies \( \sqrt{S} = 10 \) and 200 GeV. \( R \) is shown in percent and contour lines in steps of 5\% are drawn on the surface of the plot and as projection on the base. A small circle marks \( R(r = 2.5, f = 2.5, c = 1.5) \equiv 0 \), so the contour of zero \( R \) runs through this circle. At the base we also draw a line for the usual choice \( \mu_r = \mu_f \) to guide the eye. Note that in plot (d) we have multiplied \( R \) with \((-1)\) to achieve a nice presentation in the same form, i.e., the change in the low \( r \) and high \( f \) region is opposite to the one for the LO plot (c). As can be inferred from comparing the LO and NLO results at both center of mass energies in Fig. 8.1 (a) vs. (b) and (c) vs. (d), respectively, the scale dependence has been drastically reduced in NLO over the entire range of \( \mu_f \) and \( \mu_r \), which underlines the importance of the NLO results. Moreover, in NLO the choice \( \mu_f = \mu_r \) is approximately on the contour for \( R = 0 \), and \( R \) is flatter for large \( \mu_f \) and \( \mu_r \). This motivates the choice of scales, \( \mu_f = \mu_r \), which we will use henceforth. For reasonable changes of \( \mu_f \) and \( \mu_r \) in Fig. 8.1, the polarized total charm production cross section (8.9) varies by about 15\% at \( \sqrt{S} = 10 \text{ GeV} \) and 25\% at \( \sqrt{S} = 200 \text{ GeV} \) in NLO as compared

\(^2\)Also we are forced to ignore the resolved contributions. However, they are not expected to introduce major changes to the results presented here, see the discussion above (6.27).

\(^3\)For example the “ETAG33” sample of [22] has \( \langle \sqrt{S_{\gamma p}} \rangle = 194 \text{ GeV} \).
Figure 8.1: $R(r, f, 1.5)$ in percent, see (8.19), for renormalization $\mu_r^2 = r m_c^2$ and factorization $\mu_f^2 = f m_c^2$ scale variations with $\sqrt{S} = 10$ GeV: LO (a) and NLO (b), and $\sqrt{S} = 200$ GeV: LO (c) and NLO, times (-1), (d). The charm mass $m_c = c$ GeV is set to $c = 1.5$. Also shown are a $\circ$ symbol at $R(2.5, 2.5, 1.5) \equiv 0$, contour steps of 5% and a $r = f$ line at the base.
to about 45% at $\sqrt{s} = 10$ GeV and 50% at $\sqrt{s} = 200$ GeV in LO. Contrary to the naïve expectation, the scale dependence becomes slightly stronger for higher energies. But this effect mainly comes from the corner of low $r$ and high $f$. For larger $r$, the dependence on $f$ is reduced at higher energies in NLO. Note also that at $\sqrt{s} = 200$ GeV, the LO $R = 0$ contour has moved closer to the $\mu_r = \mu_f$ line. This is in contrast to $\sqrt{s} = 10$ GeV, where this line is basically the direction of strongest change. We have not studied whether this trend persists at even higher energies, since the numerical integrations become very time consuming and since LO is expected to be inadequate at high energies due to the lack of flavor excitation subprocesses.

Next we wish to examine the dependence on $m_c$. Fig. 8.2 shows $R(r, r, c)$, i.e., we now keep $\mu_r = \mu_f = \mu$ all the time, but still vary $\mu$ to see whether the $m_c$ dependence of the total polarized cross section is influenced. Again contours show steps in percent, but now they mean differences of 15% each! So we can immediately conclude that the dependence on the charm mass is much stronger than the one on the factorization and renormalization scales, in particular at lower energies. Again a small circle marks $R(r = 2.5, f = 2.5, c = 1.5) = 0$ and we show a line for $r = f = 2.25$ at the base of the plots. We see that at low energies NLO is much more stable than LO, we get about 135% variation in LO compared to about 45% in NLO in Fig. 8.2 (a) and (b), respectively. However, at large energies LO and NLO both vary by about 45%. So in NLO the dependence on $m_c$ stays roughly constant, whereas it strongly increases in LO at lower energies. It is surprising that NLO improves the stability of the predictions against variations of $m_c$. But we have set $\mu^2_f = \mu^2_r = r m_c^2$, so we indirectly probe the stability along the $\mu_r = \mu_f$ line! Obviously then the differences between LO and NLO are largely due to their behavior for $\mu_r = \mu_f$ discussed above. Note that at $\sqrt{s} = 10$ GeV the dependence on $m_c$ is least in NLO for small $r = f$ values, in particular there is little variation for low values of $m_c$. But concerning the dependence on $r$ and $f$ separately in Fig. 8.1 we would favor larger values to stay in the “flattest” region. We will use a compromise value of $\mu_r = \mu_f = 1.5$ $m_c$, which means $r = f = 2.25$, as standard value in the following. This choice is shown by the line included at the base of the plot in Fig. 8.2. It is lower than the choice $\mu_r = \mu_f = 2 m_c$ used in [34, 35], which optimized the dependence on $\mu_r$ and $\mu_f$. Here we will basically only vary $m_c$, since comparing Fig. 8.2 and Fig. 8.1 makes obvious that this will give the major part of the theoretical uncertainties. Note in particular that the changes induced by varying $m_c$ are more or less independent of the variation of $r = f$, i.e., the contours are close to being parallel to the $r = f$ axis. Finally it is perhaps more natural to use a standard value for $\mu_{r,f}$, which is not at the high edge but rather in the middle of the usual variation range $m_c \leq \mu_{r,f} \leq 2 m_c$. We will in the rest of the paper vary $m_c$ in the range from 1.4 to 1.6 GeV, instead of the larger range 1.35 to 1.7 GeV in the $R(r, r, c)$ plot, to give a rough estimate of the theoretical uncertainty. This basically amounts to taking the results for the charm mass collected in\(^4\) [1] at face value instead of using the conservative range also quoted there.

\(^4\)Note that their table shows all results converted to the running mass of the $\overline{\text{MS}}$ scheme. The pole mass we need here is approximately 20% larger.
Figure 8.2: $R(r, r, c)$ in percent, see (8.19), for charm mass $m_c = c$ GeV and renormalization scale $\mu^2_0 = r m^2_c$ variations with $\sqrt{S} = 10$ GeV: LO (a), NLO (b) and $\sqrt{S} = 200$ GeV: LO (c), NLO (d). The factorization scale $\mu^2_1 = f m^2_c$ is set to $f = r$. Also shown are a ⃝ symbol at $R(2.5, 2.5, 1.5) \equiv 0$, contour steps of 15% and a $r = f = 2.25$ line at the base.
8.2. Numerical Studies for Photoproduction

Figure 8.3: $x_T$-differential polarized anticharm photoproduction cross section $d\Delta \sigma_{\gamma p}^c/dx_T$ in LO and NLO at $\sqrt{S} = 10, 200$ GeV with the GRSV standard polarized parton densities [15]. Thick lines have $m_c = 1.5$ GeV, thin lines with largest positive peak have $m_c = 1.4$ GeV, and the other thin lines have $m_c = 1.6$ GeV. In NLO the thin lines are connected to form a band. We have set $\mu_r^2 = \mu_f^2 = 2.25(m_c^2 + p_T^2)$. The curves for $\sqrt{S} = 200$ GeV are multiplied by 1/7.

We will now take a look at $p_T$, or equivalently $x_T$, see (8.12), differential results. The reason is that we wish to derive a good value for an acceptance cut on $p_T$ in order to enhance the asymmetry. We expect that the COMPASS experiment [31] will not be able to accurately measure differential distributions. But they are still useful as a guide for possible cuts. Fig. 8.3 shows $d\Delta \sigma_{\gamma p}^c/dx_T$ for $\sqrt{S} = 10$ GeV and 200 GeV. We use $\mu_r^2 = \mu_f^2 = 2.25(m_c^2 + p_T^2)$ here, since it can be expected that $p_T^2$ becomes a relevant scale when it is not integrated out. This choice reduces to the standard choice for the total cross section $\mu_r = \mu_f = 1.5m_c$ in the limit of small $p_T$. Here and in the following we always plot as thick line the result for $m_c = 1.5$ GeV and for the thin lines we vary the

---

5There are changes in the ballpark of 10% in the following differential curves as compared to [35] due to the scheme inconsistency corrected in [37]. For the total polarized cross section the changes are smaller.
charm mass from $m_c = 1.4$ GeV to $m_c = 1.6$ GeV. By adding $p_T^2$ in our scale definition we shift towards larger $\mu_r$ and $\mu_f$, where the dependence on independent $\mu_r$ and $\mu_f$ variations becomes less and the dependence on $m_c$ slightly larger for the total polarized cross section. Thus varying $m_c$ still is a reasonable estimate for the theoretical uncertainty, at least for the lower energy $\sqrt{S} = 10$ GeV, and with an integrated cross section in mind. The independent variation of $\mu_r^2$ and $\mu_f^2$ as $a(p_T^2 + m_c^2)$ with $a = 1/4, \ldots , 4$ has already been shown in Fig. 10 of [35]. Note that the range of $a$ chosen there is rather conservative and yields large uncertainties. The lower and upper limits in this case come from one scale set to $a = 1/4$ and the other set to $a = 4$. Since $(m_c^2 + p_T^2)/4 < m_c^2$ for $x_T \lesssim 0.54$ at $\sqrt{S} = 10$ GeV (for $x_T \lesssim 2.6 \cdot 10^{-2}$ at $\sqrt{S} = 200$ GeV), the large uncertainties of the differential distribution shown in Fig. 10 of [35] are mainly due to a scale choice lower than the lowest one $\mu_{r,f} = m_c$ used for the total cross sections. For $\sqrt{S} = 200$ GeV varying
\( m_c \) will underestimate the theoretical uncertainty, as \( p_t \) can become quite large and then dominates the sum \( m_c^2 + p_t^2 \). We nevertheless show the \( m_c \) variation in order to compare with \( \sqrt{S} = 10 \text{ GeV} \) and because the total polarized cross section uncertainty is dominated by it, as we just showed. In Fig. 8.3 the NLO curves are connected to form bands and we have multiplied the curves for \( \sqrt{S} = 200 \text{ GeV} \) by \( 1/7 \) in order to fit them into the same plot. We see that in NLO the variation with \( m_c \) is slightly reduced in comparison to LO. On the other hand going to higher energies suppresses the variations more strongly than for the total polarized cross section. The reason is that the amplitude of the oscillating \( x_T \)-differential polarized cross section is both larger positive and larger negative for lower \( m_c \), so that in the integration part of the larger relative variations cancel.

The oscillating behavior in \( x_T \) is explored further in Fig. 8.4 for \( \sqrt{S} = 10 \text{ GeV} \) only. We show the result for three different sets of polarized parton densities, GRSV standard (solid line), DSS set 3 (dot-dashed line), and GS A (dashed line) [15, 17, 18]. The prediction for the polarized cross section turns negative at approximately the same \( x_T \), no matter which parton distribution is chosen. Also the variation of \( m_c \) does not strongly change the position of the zero. We see that by taking a cut \( x_T \lesssim 0.25 \) or equivalently \( p_T \lesssim 1.2 \text{ GeV} \), the negative contributions are cut off and hence the total polarized cross section is enhanced. On the other hand the unpolarized cross section, which is shown multiplied with a factor 1/2.5 by the dotted line, does of course not oscillate. Thus the cut takes out a significant part of the unpolarized cross section. Hence we expect that the asymmetry \( A = \Delta \sigma / \sigma \) should be strongly enhanced by this cut, since the numerator grows and at the same time the denominator is diminished. This should take place for all the polarized parton densities and \( m_c \) values we are exploring.

We see exactly the expected features in Fig. 8.5, which shows the total NLO anticharm photoproduction spin asymmetry \( A_{\mu}^{CP} \) with a cut \( p_T \leq 1.2 \text{ GeV} \). Comparing the bands for the GRSV standard parton density prediction with cut (solid lines) and without cut (dotted lines) at NLO, we see that the asymmetry is strongly enhanced, by about 60\% at \( \sqrt{S} = 10 \text{ GeV} \)! Examining the effect of introducing different parton densities, we see that there are strong differences in the predicted asymmetry. Certainly these differences are larger than the theoretical uncertainties of our calculation, estimated here again by varying \( m_c \). Also compared to the expected statistical error for the COMPASS experiment [31] the situation looks favorable. We use an expected asymmetry error 20\% larger than the estimate \( \delta A_{\mu}^{CP} \approx 0.051 \) of [31]. This corresponds to the loss of statistics due to the cut, i.e., for the unpolarized cross section \( \sqrt{\sigma_{\text{no cut}} / \sigma_{\text{cut}} \approx 1.2} \). The appropriately larger error is shown by the point with error bar placed on the GRSV standard curve. It should be possible to distinguish the different parton densities, even when the theoretical uncertainties are taken into account.

However, for a small gluon density like in the DSS set 3 fit, an improved experimental measurement is required in order to unambiguously measure the asymmetry. Smaller \( \sqrt{S} \) lead to a larger spread of the predictions, but COMPASS will not be able to measure at lower \( \sqrt{S} \). Higher energies are obviously not preferred for this measurement. There is a simple reason why we show no LO predictions. For these values of \( \sqrt{S} \) only large \( x \gtrsim 0.1 \)
Figure 8.5: NLO anticharm photoproduction spin asymmetry $A_{\gamma p}^c$ with a cut $p_T \leq 1.2$ GeV using the GRSV standard, DSS set 3, and GS A polarized parton densities [15, 17, 18]. For the unpolarized cross section GRV'94 parton densities [62] were used. The thick lines have $m_c = 1.5$ GeV, the upper thin lines have $m_c = 1.4$ GeV, and the lower ones have $m_c = 1.6$ GeV (order reverses at $\sqrt{S} \lesssim 6$ GeV for GRSV standard). The GRSV standard curves are connected to form a band. We have set $\mu_r^2 = \mu_f^2 = 2.25(m_c^2 + p_T^2)$. GRSV standard curves without $p_T$-cut and the expected error at COMPASS [31], see text, are also shown.

are probed. In Fig. 8.6 we plot the ratio of the NLO to the LO gluon for several different polarized gluon densities in this large $x$ region. We see that for GRSV standard and DSS set 3 [15, 17], the NLO gluon can be up to a factor two larger than the LO gluon. For GS A [18] the situation is even worse, here the NLO gluon is up to 15 times larger than the LO gluon. This massive enhancement is completely accidental in the parton density fits, since the polarized gluon is currently not constrained at these values of $x$. In comparison the NLO to LO ratio for the unpolarized GRV'94 [62] gluon stays fairly flat and close to unity up to very large $x$. Due to the artificially enhanced gluonic contribution we would obtain large differences between LO and NLO predictions, see [34]. One could for example use the NLO parton densities also for the LO curves to avoid this [34, 96]. But as we have argued in Chap. 7, NLO is here the first order in which all important classes of graphs are included. So we refrain from showing LO curves, they can be found in [34].
Figure 8.6: Ratios of NLO to LO polarized gluon distributions in the large $x$ region. Shown is $\Delta g(\text{NLO})/\Delta g(\text{LO})$ for the GRSV standard [15], DSS set 3 [17], and GS A [18] polarized parton densities. For comparison the ratio NLO to LO for the unpolarized GRV’94 [62] parton densities is also shown.

Unfortunately, a measurement of $A_{\gamma p}^c$ at collider energies, where one could access smaller $x$, appears to be not feasible, since $A_{\gamma p}^c$ is at best of the same size as the expected statistical error for such a measurement [33]. This also does not improve for $p_T$ or $y$ differential charm distributions. Since $A_{\gamma p}^c$ already appears to be unmeasurable at HERA, the prospects for a meaningful measurement of $A_{\gamma p}^b$ seem to be not very promising at first, since bottom cross sections are smaller due to the larger $b$ quark mass and the smaller heavy quark charge $(e_b/e_c)^2 = 1/4$. However, $b$ quarks are experimentally much easier to detect, e.g., through their longer lifetime (secondary vertex tag), which might compensate these shortcomings. By looking at the curves for $\sqrt{S} = 200$ GeV in Fig. 8.3, which is for anticharm but qualitatively shows what is to be expected for antibottom as well, we can guess that introducing a cut in $p_T$ will also help here. However, experimentally it will not be possible to measure very small $p_T$ at HERA, so we use a cut $p_T \geq 1.5$ GeV instead, i.e., now we are cutting off the positive part of the polarized cross section. Thus in Fig. 8.7 we turn to the longitudinal spin asymmetry $A_{\gamma p}^b$ of polarized antibottom photoproduction in NLO at the polarized HERA option [28] for three different sets of polarized parton
Figure 8.7: NLO antibottom photoproduction spin asymmetry $A_{\gamma p}^b$ with a cut $p_T \geq 1.5$ GeV using the GRSV standard, DSS set 3, and GS A polarized parton densities [15, 17, 18]. For the unpolarized cross section GRV'94 parton densities [62] were used. The thick lines have $m_b = 4.5$ GeV, the lower thin lines have $m_b = 4.4$ GeV, and the upper ones have $m_b = 4.6$ GeV. We have set $\mu_F^2 = \mu_R^2 = 2.25(m_b^2 + p_T^2)$. For GRSV standard varying $\mu_F^2$ and $\mu_R^2$ independently with $a(m_b^2 + p_T^2)$, $m_b = 4.5$ GeV, and $a = 1, \ldots, 3.5$ yields the outer thin lines. GRSV standard curves without $p_T$-cut and points with the expected statistical error according to (8.20) are also shown.

Again thin lines show the variation with the heavy quark mass, here from $m_b = 4.4$ GeV to $m_b = 4.6$ GeV, and the thick line is for the central value $m_b = 4.5$ GeV. Choosing a more conservative range hardly matters at the higher $\sqrt{S_{ep}}$ mainly probed by experiment. The results obtained for the different sets of parton densities are well separated and sensitive to the different $\Delta g$, but $A_{\gamma p}^b$ is extremely small. The points with error bars in Fig. 8.7 illustrate the expected statistical accuracy for such a measurement at HERA estimated via

$$
\delta A_{\gamma p}^b \approx \frac{1}{P_e P_p} \frac{1}{\sqrt{\varepsilon_b \sigma_{\gamma p}}}
$$

(8.20)
assuming a polarization $P_e P_p \simeq 0.5$ of the electron and proton beams, an (optimistic) integrated luminosity of $\mathcal{L} = 500 \text{ pb}^{-1}$ [28], and an optimal detection efficiency of $\varepsilon_b = 0.05$ [97]. Note that we do not bin in $\sqrt{S_{\gamma p}}$ here, i.e., the errors are estimated at the point where they are drawn. Since HERA is an $ep$, not $\gamma p$, collider, the center of mass energy of the $\gamma p$ system varies and usually one averages over a large $\sqrt{S_{\gamma p}}$ bin.

![Graph](image-url)

**Figure 8.8:** $y$-differential polarized anticharm photoproduction cross section $d\Delta \sigma_{\gamma p}^\gamma / dy$ in LO and NLO at $\sqrt{S} = 10$ GeV with the GRSV standard densities [15] as measured in the hCMS. The thick lines have $m_c = 1.5$ GeV, the thin lines with largest positive peak have $m_c = 1.4$ GeV, and the ones with smallest positive peak have $m_c = 1.6$ GeV. We have set $\mu_r = \mu_f = 1.5 m_c$. The initial light quark contributions to the NLO curves are shown separately, for them the $m_c = 1.4$ GeV curve has the largest negative peak and so on. For comparison analogous unpolarized curves with NLO GRV'94 densities [62] are shown divided by 10. They are also mirrored, i.e., we plot $d\sigma(-y)$.

For comparison we also display the GRSV standard curves without $p_T$-cut as dotted lines. They show that we succeeded in cutting off the positive part of the polarized cross section, which otherwise cancels the negative part, i.e., the total asymmetry without $p_T$-cut is close to zero for these energies. Instead we now see a decent separation of the predictions for different parton densities, which yield asymmetries distinguishable from
Figure 8.9: $x_F$-differential polarized anticharm photoproduction cross section $d\Delta \sigma^p_{\gamma p}/dx_F$ in LO and NLO at $\sqrt{S} = 10$ GeV with the GRSV standard densities [15] as measured in the hCMS. The thick lines have $m_c = 1.5$ GeV, the thin lines with largest positive peak have $m_c = 1.4$ GeV, and the ones with smallest positive peak have $m_c = 1.6$ GeV. We have set $\mu_r = \mu_f = 1.5 m_c$. The initial light quark contributions to the NLO curves are shown separately, for them the $m_c = 1.4$ GeV curve has the largest negative peak and so on. For comparison analogous unpolarized curves with NLO GRV'94 densities [62] are shown divided by 13. They are also mirrored, i.e., we plot $d\sigma(-x_F)$.

zero except perhaps for the small DSS set 3 gluon. We see that the dependence on the bottom mass is quite small, in particular at larger energies. Since we know that we underestimate the theoretical uncertainty by only varying the bottom mass, we also vary $\mu_r^2$ and $\mu_f^2$ independently according to $a(m_b^2 + p_T^2)$, where $m_b = 4.5$ GeV and $a = 1, \ldots, 3.5$. This gives the outer thin lines for the GRSV standard densities. We see that this is not a much larger uncertainty than for the $m_b$ variation. The uncertainty also basically vanishes for larger energies, so we see that from a theoretical point of view (anti)bottom photoproduction allows very precise predictions. One has to keep in mind

---

This is a less conservative choice than the usual $a = 1/4, \ldots, 4$. We limit the lowest possible scale to $\mu_{r,f} = m_b$ and vary $a$ by $\pm 1.25$ around the standard value $a = 2.25$.
though that we have calculated here only the direct (point-like photon) part of the cross section as a first approximation, see the discussion above (6.27). Thus the uncertainties due to the resolved contributions have not been taken into account. Also we will discuss in the next section that in the unpolarized case theoretical predictions describe bottom data less well than charm data. This is unexpected, since the larger bottom mass should provide a better scale for perturbation theory. Without solving this issue the usefulness of future polarized bottom data will be limited, at least for the extraction of the polarized gluon density $\Delta g$.

Finally, let us turn to further results for differential distributions. Although their experimental relevance seems to be remote, apart from $y$ and $x_F$ acceptance cuts, a comparison of the LO and NLO distributions is of theoretical interest to understand in which kinematical regions the corrections are most relevant. In Fig. 8.8 and Fig. 8.9 we show the polarized rapidity $y$- and $x_F$-differential anticharm photoproduction cross sections as measured in the hadronic center of mass system (hCMS). We here revert to $\sqrt{S} = 10$ GeV and since $p_T$ is integrated over the entire kinematical range, we again choose $\mu_f = \mu_r = 1.5 m_c$. The distributions are asymmetric in $y$ and $x_F$ and the heavy quark is dominantly produced "backward" with respect to the incoming photon, i.e., in the direction of the proton. The NLO results are always larger than the LO ones and deviate in shape, having a larger backward peak. In both figures the unpolarized distributions, scaled down to approximately the size of the polarized one, are shown for comparison. Note that we have mirrored the unpolarized distributions in order to disentangle the lines. This means, we have plotted the unpolarized distributions as a function of $-y$ and $-x_F$, respectively. We see that the more complicated shape only emerges in the polarized case in NLO. The additional contribution with light quarks in the initial state at NLO is included and also shown separately. It appears to be basically negligible in the entire $y$ and $x_F$ range at this energy. We have also again varied the charm mass, but this does not change the general appearance of the distributions. However, the induced variations are quite large and for the NLO polarized case lead to a more pronounced peak structure for lower charm masses. We see however that the structures we observe in these cases do not immediately suggest simple cuts in order to enhance the asymmetry, as had been the case for $p_T$.

### 8.3 Current State of Experiment vs. Theory

To make a fair assessment of the practical usefulness of our results, we now examine how well heavy quark production theory and experimental data have matched in the past. Our conclusion that heavy quark reactions are useful for the determination of the polarized gluon density $\Delta g$ is based on the theoretical predictions of the last section, but the experience in the unpolarized case raises some serious caveats. However, we will find that we are in a “win-win” situation, provided the future experiments also measure the corresponding unpolarized reactions and possibly obtain independent information about $\Delta g$. Then we will either improve our knowledge about $\Delta g$ or obtain valuable information
for the solution of the “heavy quark enigma” discussed below. The scope of this section is limited. First, we will focus exclusively on the (QCD) production of open charm and bottom. In particular we will not discuss heavy quarkonium production, like the production of the charmonium bound state $J/\psi$. Concerning heavy quarkonia, we just remark that the sophisticated nonrelativistic QCD (NRQCD) calculations seems to be in serious trouble due to preliminary experimental data on the transverse polarization of charmonium states at high $p_T$ [98]. It remains to be seen whether this can be cured. Perhaps other approaches like the color evaporation model (CEM), which has been revived recently [99] but was proposed over twenty years ago, see for example [61], now become more attractive. However, at least there are alternatives to the color-singlet model (CSM) available, which do not utterly fail to describe the direct production cross section of $J/\psi$ and $\psi'$, as the CSM does [100].

Second, we can of course only comment on comparisons of unpolarized theoretical calculations and data, as we are still waiting for the first polarized experimental results. Third, we are relying here mainly on the work of other authors. In principle we could of course use our unpolarized results and compare them to part of the existing data. However, we have not yet completed the NLO hadroproduction calculation, so thus far we have concentrated on deriving the missing reduced partonic cross sections. The hadron level results shown in the last section are thus first rough predictions. For in-depth phenomenological studies of photoproduction at lepton-nucleon colliders, we should include the convolution of the photoproduction cross section with the photon distribution in the electron according to the Weizsäcker-Williams approximation (WWA) [101, 102, 103]. Then we could compare directly to lepton-nucleon data without depending on any approximate “WWA flux factor” treatment. Also the “resolved” photoproduction processes should be taken into account. Finally, experiments do not really detect heavy quarks, but rather (the decay products of) hadrons. Thus we should include fragmentation functions like the one suggested by Peterson et al. [104] to model hadronization. These improvements will be implemented in future versions of our program.\footnote{A version including the WWA exists, but has not been thoroughly tested yet.} Note that we can expect the numerical evaluation to become much slower then, since more convolutions are needed. So for the time being we will turn to the comparisons available in the literature.

We begin by examining fixed-target production of open charm, using the results of [106]. A convenient compilation of experimental results with references is provided there, so we refer the reader to [106] concerning the experiments mentioned in the following. The total cross sections both for hadroproduction (experimental collaborations for charm in pion-nucleon – E653, E769, NA27, NA32, E769; charm in proton-nucleon – E653, E769, E743, NA27, NA32; bottom in pion-nucleon – E653, E672, E706, NA10, WA78, WA92; bottom in proton-nucleon – E605, E771) and photoproduction (experimental collaborations for charm in photon-nucleon – E687, E691, NA14/2) are well described by the NLO unpolarized calculations within the conservatively estimated theoretical uncertainty. The covered center of mass energies are about 20 to 40 GeV in hadroproduction and 10 to 20 GeV in photoproduction. The major theoretical uncertainty is due to the variation
of the heavy quark mass in the case of charm, as expected from our results of the last section. In the case of bottom this uncertainty is also sizable, but variations of $\mu_{R, F}$ still dominate the uncertainty there. Compared to the predictions of [106], the data for the hadroproduction of charm prefer the value $m_c = 1.5$ GeV we have been using, but values down to $m_c = 1.2$ GeV are possible. High values like $m_c = 1.8$ GeV are disfavored. In photoproduction $m_c = 1.5$ GeV again gives the best description. Here both high and low values of $m_c$ give worse agreement. However, this always just means that the overall agreement with the broad band of theoretical uncertainties obtained for the conservative range $m_c/2 \leq \mu_r \leq 2m_c$ with $\mu_f = 2m_c$ is better in one case than the other. Experimental data tend to scatter within the uncertainty band and sometimes are inconsistent, e.g., E687 vs. E691 in photoproduction. The variations tried in [106] for the bottom mass from 4.5 to 5 GeV all are in accord with the data in the same sense. Here both scales

Footnote: Note that the uncertainty due to $m_b$ variations increases for lower c.m. energies in Fig. 8.7.
have been varied in the conservative range $m_b/2 \leq \mu_r \leq 2m_b$. Furthermore, the authors of [106] have also varied $\Lambda_{\text{NLO}}$. Apart from correlations with the parton densities, this is equivalent to an even larger range of $\mu_r$ being probed, up to the point where in the case of charm the variations "induce values of $\alpha_s(m_c)$ too large to be used in a perturbative expansion" [106].

Since we can calculate the direct part of the total photoproduction cross section with our results and have assumed that the resolved contribution is small at these energies, we can check their conclusions for this case. We will adopt here the opposite approach to [106]: since they have already explored the possible theoretical uncertainty up to the inapplicability of perturbation theory itself, we wish to see if "optimistic" scale variations are still compatible with data. So in Fig. 8.10 we present curves for $\sigma_{\gamma N}^{\mu_2^2}$ with three choices for the charm mass $m_c = 1.4$, 1.5, and 1.6 GeV as dot-dashed, solid, and dashed lines, respectively. The thick lines are obtained for our standard choice $\mu_r^2 = \mu_0^2 = 2.25m_c^2$, whereas the thin lines are obtained for independent variations of $\mu_r^2$ and $\mu_0^2$ by $\pm1.25m_c^2$. We use the GRV'94 parton densities [62] and keep $\Lambda_{\text{NLO}} = 200$ MeV fixed. Thus our Fig. 8.10 corresponds to Fig. 3 in [106]. We see that even with our "optimistic" choices, the overall theoretical uncertainty forms a band broad enough to still "agree" with the available data [105]. Note that the dependence on the mass scales is worse in the unpolarized case than in the polarized case. It is also evident that the experiments do not match well with each other in the region where they overlap and also there seem to be differences in the energy dependence. With our "optimistic" scale variations one cannot say that one choice of $m_c$ fits best, rather one could claim that $m_c = 1.5$ GeV is a compromise value which fits all three experiments to some extent. We draw the conclusion for the future COMPASS [31] measurement that in order to be able to extract $\Delta g$ from the total charm spin asymmetry one should measure the unpolarized total cross section as well. Though a rough agreement with the NLO QCD prediction is found, the "optimistic" theoretical uncertainty we have explored here, which were basically also used for the predictions of the last section, is the minimum required to "fit" current unpolarized experiments, mainly because the experiments disagree with each other. An unpolarized COMPASS measurement could be very helpful in that respect.

As a final point concerning the unpolarized fixed target experiments we note that in the differential distributions usually the introduction of intrinsic transverse momentum of the partons (a $k_T$ "kick") is required to match the theoretical description with the data. Strangely enough the NLO QCD predictions for pure heavy quarks, i.e., without hadronization, fit the hadroproduction data of the WA92 and E769 experiments on $p_T$- and $x_F$-distributions well. However, the introduction of fragmentation functions [104] softens the $p_T$-distribution and then a rather large $k_T$-kick $\langle k_T^2 \rangle = 1 - 2$ GeV$^2$ is needed to agree with that data. The $x_F$-distributions of most other hadroproduction experiments are harder than the predictions for pure heavy quarks, in particular in the case of "leading particles", see [106] for details. Here the introduction of other non-perturbative

---

\footnote{We use the approximation $\sigma_{\gamma N}^{\mu_0^2} = (\sigma_{\gamma N}^{\mu_2^2} + \sigma_{\gamma N}^{\mu_0^2})/2 \approx \sigma_{\gamma p}^{\mu_0^2}$, which is valid since charge asymmetry and quark contributions are small. The data have been read off the plots in [105].}
QCD phenomena like beam-drag effects [107] may be necessary, we will briefly comment on this below. However, we are mainly interested in the $p_T$-distributions here, since we want to introduce $p_T$-cuts. In Fig. 8.11 we show Fig. 6 of [106], which compares the NLO QCD prediction for the unpolarized $p_T^2$ distribution with data from the E687 and E691 collaborations. We see that the introduction of fragmentation functions (they used the form of [104] with the parameter $\epsilon_c = 0.06$) is required to describe the data. But the good news is that the $k_T$ kick does not significantly change the prediction for variations $<k_T^2> = 0.5 - 2$ GeV$^2$ and a fair description of the data is achieved. Thus we should be able to estimate the non-perturbative effects with good accuracy when using a $p_T$-cut to enlarge the asymmetry in the polarized measurement. However, it would be preferable if the COMPASS collaboration [31] would scan over different $p_T$-cut values and publish the corresponding integrated unpolarized cross sections. That would allow us to test our understanding of this issue. All in all we think that the prospects for a meaningful measurement of the polarized gluon density $\Delta g$ at COMPASS are still good after these considerations, provided the unpolarized cross section can be determined. Also one can check this determination of $\Delta g$ against an independent measurement of the gluon polarization at COMPASS, which uses correlated high $p_T$ hadron pairs [108].

![Figure 8.11: $p_T^2$-differential distribution for unpolarized charm production in $\gamma N$ collisions vs. experimental data. The solid line shows the “pure” NLO QCD prediction for $m_c = 1.5$ GeV, the other lines include fragmentation (according to [104] with $\epsilon_c = 0.06$) and different amounts of intrinsic $k_T$ assumed for the incoming partons. See [106] for details, this is their Fig. 6.](image)

Next we turn briefly to the HERA $e p$ collider. First we remark that the description of charm production in deep inelastic scattering (DIS) has been very successful so far. The data for the charm tagged content of the inclusive proton structure function $F_2$, called $F_D$, are well described by theoretical predictions, see for example [24]. Data on differential distributions are also in accordance with theory as is conveniently summarized in [109].
However, for the distributions depending on the longitudinal momentum, like $x_F$, one has to include non-perturbative effects like beam-drag to obtain satisfactory agreement. The idea is basically that the produced charm quark is usually color-connected to the beam remnant of the incoming particle [107, 110]. Thus it can be “dragged” along in the direction of the outgoing remnant and gain energy and momentum. The net effect is that more than expected charmed hadrons are produced “forward” (in the direction of the remnant), and less are produced “backward”. This mechanism was first proposed for the fixed target data, but also works well here. It is encouraging that charm production in DIS is described so well by NLO QCD calculations. But of course the large virtuality of the photon in DIS may very well be responsible for that success. So we will now turn to photoproduction. Photons of (almost) zero virtuality, where the electron is scattered by a small angle, are dominant in the heavy flavor production at HERA. In particular comparisons with (preliminary) ZEUS results from the large statistics sample collected in the 1996 and 1997 runs with an integrated luminosity of 37 pb$^{-1}$ are interesting. For charm production once more increased forward production is observed. For the data taken with photon-gluon c.m. energies between 130 and 280 GeV [111], beam-drag effects once more may cure the observed discrepancies for differential distributions between theory and data [112]. But this seems to work less well for events in the low photon-gluon c.m. energy range between 80 and 120 GeV [113]. We note that the successful gluon extraction from photoproduction [22] is based on two older data sets from 1994-96, with an integrated luminosity of (10.7 + 10.2) pb$^{-1}$. The results of this analysis were already shown in the right half of Fig. 1.2. Here the problems in the differential distributions with forward production seem to be less severe and occur only at high $p_T$. Furthermore, the total $c\bar{c}$ pair photoproduction cross section is compatible with theory within errors [106]. Thus it is in line with the fixed target measurements, in spite of being measured at energies one order of magnitude larger. We find that at the higher energy of HERA the picture of charm production has become less clear. However, we still conclude that charm production at HERA is or will be describable with currently available theoretical methods, if non-perturbative effects like beam-drag are taken into account for the differential distributions. But we have already mentioned in Chap. 6 that charm spin asymmetries at HERA will probably be unmeasurable anyway [33].

So we will now turn to bottom production. A general statement can be made about bottom production at colliders, both for photo- (electro-) and hadroproduction: the theoretical predictions are about a factor two (or more) off! H1 measures a visible cross section $\sigma (ep \rightarrow b\bar{b}X \rightarrow \mu X')$ of about 176 pb, compared to a NLO QCD prediction of 104 pb [116]. Their estimate of the experimental error towards smaller values is about 23 pb (statistical and systematical error added in quadrature), whereas they estimate the theoretical uncertainty to be 17 pb. However, it would be interesting to examine the role of the AROMA Monte Carlo event generator [117] used in the extraction of their data more closely, since after all the prediction of the same AROMA program for the visible cross section is$^{10}$ 38 nb. A second method of measuring the production of $b\bar{b}$ pairs at

---

$^{10}$The LO QCD prediction is 69 nb, so the AROMA prediction is even lower than LO.
Figure 8.12: Bottom quark production data from CDF and DØ compared with the NLO QCD prediction. The theoretical uncertainty displayed by the band is associated with $\mu_r$, $\mu_f$, and $m_b$ variations. The dependence of the integrated cross section on a cut $p_T > p_T^{\text{min}}$ is shown. This is Fig. 11 of [114].

H1 gives similar large discrepancies between the experimental measurement and the LO ARONA prediction [118]. Finally, preliminary experimental results from ZEUS on $b\bar{b}$ production also show a factor 4 disagreement of data with the predictions from a different LO Monte Carlo [119, 112]. Even if the evidence from HERA is not as clear yet as one may wish, the results for hadroproduction, mainly from the TEVATRON at FERMILAB, have stood the test of time. Two recent articles [114, 120] conveniently summarize the complex situation for bottom hadroproduction, details and references can be found therein. Fig. 8.12, which is Fig. 11 of [114], shows what is typically found at the TEVATRON by the CDF and DØ collaborations: While the shape of the NLO QCD prediction is fine, the normalization is wrong. Displayed in Fig. 8.12 is the integrated $p_T$-distribution for bottom quark production depending on a $p_T$-cut, i.e., a similar plot as our Fig. 2.5 but with bottom, at a c.m. energy of 1.8 TeV and compared to NLO QCD calculations. We find a ratio “data/theory~ 2.5” in this plot. The data displayed there have been taken in the central rapidity region, for forward production the shape still agrees, but then
“data/theory $\approx 4$” [120]. A considerable amount of effort has been spent on improving the theoretical description of these data, which have been consolidated over the years, basically without avail\(^{11}\). This is very puzzling, since we can describe charm production to a considerable extent, as we have just seen. Thus we are in the strange situation that NLO QCD seems to be working better at the “dangerously low” scale $m_c^2 \approx 2.25 \text{ GeV}^2$, whereas it fails drastically at the “safe” scale $m_b^2 \approx 20.25 \text{ GeV}^2$. This deserves to be called the “heavy quark enigma”. But the fact that NLO QCD at least describes the shape of the data offers some hope. Furthermore, Fig. 8.13, taken from [115], shows that NLO QCD also has the right energy dependence! In this plot the ratio of the $p_T$-integrated bottom production cross section measured at two different energies 630 GeV and 1.8 TeV is displayed and obviously within the rather large experimental errors the NLO QCD prediction fits perfectly. The D0 errors are expected to become smaller after correlations have been taken into account. Only CDF and D0 data have been used in order to reduce common systematic errors, but older UA1 data at $\sqrt{S} = 630 $ GeV are compatible [106].

\(^{11}\)If $\alpha_s$ is maximized by an extreme choice of scales, then theory can fit the data [106].
What does all this mean for our plan of extracting the polarized gluon distribution $\Delta g$ from bottom production? Obviously it is seriously compromised, since we cannot be sure that our theoretical treatment is correct. But it looks as if a common trend of all bottom measurements in photoproduction (electroproduction) and in hadroproduction is that basically only the normalization is off by a factor. Let us assume that a polarized collider is able to measure the unpolarized cross section separately and can perform at least one independent measurement of $\Delta g$ using a different process. In this case we should be in a “win-win” situation: Either the normalization of the polarized measurement is wrong by the same factor we have determined in the unpolarized case, i.e., the effect is not spin-dependent. In this case of course the spin asymmetry $d\sigma/d\sigma$ is not affected and we would find it to be compatible with a prediction that also fits the independent $\Delta g$ determination. So then we can go ahead and measure $\Delta g$ by determining the asymmetry, in spite of the fact that $d\sigma/d\sigma$ is off. Or the normalization of the polarized measurement is not the same, i.e., a $\Delta g$ that fits the independent polarized measurement does not yield the experimental bottom spin asymmetry, when the theoretical prediction is multiplied with the factor determined by unpolarized bottom production. The information that a spin-dependence is observed could then possibly provide a tool for solving the “heavy quark enigma”? In practice of course the question will be, whether the experimental accuracy is good enough to distinguish the two cases. But here the rather large normalization factors involved may be of advantage.

Polarized HERA and RHIC fulfill the conditions mentioned above, the corresponding unpolarized measurement has or will be done and several independent measurements of $\Delta g$ are planned [28, 32]. Furthermore we note that RHIC will perform a first measurement of hadroproduction of open charm at collider energies, in addition to open bottom production. Thus they will be able to compare with open charm production at fixed target experiments and at HERA, with bottom production at HERA and at FERMILAB, and internally the results for both flavors. Their planned c.m. energies of 200 and 500 GeV are perfect for bridging the energy gap between HERA and FERMILAB. We conclude that in spite of the “heavy quark enigma”, measurements of polarized bottom production still make sense. Polarized hadroproduction of charm at RHIC is still expected to be a good candidate for measuring $\Delta g$, if we can assume that the situation will not be worse than what has been found at HERA for photoproduction of charm. However, the HERA results suggest, that we may have to consider non-perturbative effects like intrinsic $k_T$ to achieve consistency with differential charm data. It may be possible to test some of these non-perturbative model assumptions using other observables, for example azimuth correlations of the bottom pair were measured at the TEVATRON and disfavor large intrinsic $k_T$ in their bottom production reactions [114]. To sum up, we conclude for all the mentioned experiments that polarized heavy quark production can be used to determine $\Delta g$, but that the corresponding unpolarized measurement is required in order to check the validity of the theoretical methods. Furthermore, independent measurements of $\Delta g$ using other processes at the same experiment should be used as a cross check.
Chapter 9

Summary

In this thesis we have presented the first complete NLO QCD calculation of the spin-dependent production of heavy quarks in collisions of (point-like) photons and hadrons. Furthermore, we have included our work on the spin-dependent hadroproduction of heavy quarks. In order to obtain the full NLO QCD corrections for the latter reaction, we still have to sum and simplify the already calculated gluon-gluon virtual loop contributions. All other partonic cross sections of these two processes have been completed and are documented here. We have tried to provide a sort of mini-review of the methods applied in our calculation: On one hand, we explain how they are derived from the basic framework of (perturbative) QCD. On the other hand, we demonstrate how they are used efficiently in practice. To the best of our knowledge, some of the techniques have not been explained before either in detail, like the automatic partial fractioning of angular variables, or at all, like the systematic expansion of hypergeometric functions. We hope that it will prove advantageous for future perturbative QCD calculations that all the needed methods now have been collected in one reference.

Our main goal has been to provide the theoretical basis for an experimental determination of the polarized gluon distribution $\Delta g$ in open heavy quark production. For this reason we have presented predictions for spin asymmetries at experiments that will either take data soon (COMPASS [31] and RHIC [32]) or have a chance to be realized in the near future (polarized HERA [28]). We have improved our previous hadron level predictions [34, 35] by investigating the theoretical uncertainties due to the not precisely known heavy quark (pole) mass and by using cuts on the transverse momentum to enhance the spin asymmetries. One should keep in mind that our NLO calculations are indispensable for a meaningful interpretation of future experimental data: First, our NLO predictions are much more stable against variations of the renormalization and factorization scales than the LO ones. Second, in the reactions considered here several Feynman graph topologies occur for the first time in NLO, which yield large contributions both close to the production threshold and at high energies. Thus LO calculations may be misleading and should ultimately be replaced by NLO ones. Finally, we have discussed in this paper the current state of comparisons between theory and experimental data in the analogous unpolarized
case. From this discussion we conclude that a measurement of only the ratio of polarized and unpolarized cross sections will not be sufficient. The unpolarized cross section itself has to be measured, if our goal to determine $\Delta g$ is to remain realistic.

After this general overview, we now give a brief description of the salient features of our work chapter by chapter. In the introduction we have emphasized that the full QCD improved parton model is required to describe experimental data on the spin of the nucleon and that the polarized gluon distribution $\Delta g$ represents the major remaining uncertainty of this model. Polarized exclusive reactions can be used to determine $\Delta g$ better and open heavy quark production is our suggestion. Chap. 2 shows how one can obtain polarized and unpolarized cross sections simultaneously by projecting onto helicities, which makes checks against previous unpolarized calculations possible. Also the LO cross sections and the $2 \to 2$ phase space have been derived there in $n = 4 + \varepsilon$ dimensions for later use with the dimensionally regulated NLO pieces.

The treatment of the virtual loops occurring in NLO has been elucidated in the next chapter. The Passarino-Veltman decomposition [47] of the occurring tensor integrals has been derived there. This decomposition is simple in principle, but the results are very lengthy. Take for illustration a 4PF tensor integral of third rank, it has thirteen different Lorentz covariant structures, so one has to calculate thirteen parts for just one matrix element. Each of these parts is multiplied by a scalar coefficient, which is in general a complicated function of basic scalar integrals, invariants, and in particular also of the heavy quark mass. We have constructed a program that computes these coefficients, have checked the lengthy general expressions, and have simplified them for each specific case.

Second, the re-calculation of all the needed basic scalar integrals [44], which we have included here, was non-trivial in the case of vertex and box integrals. The main problems are the calculation in non-integer $4 + \varepsilon$ dimensions, the branch cuts of the occurring functions, and the increased complexity of the integral kernels due to the non-vanishing heavy quark mass.

In Chap. 4 we have spent some time on the renormalization procedure, since the $\overline{\text{MS}}_m$ scheme we employ is widely used, but not well documented in the literature. We have demonstrated how subtracting the heavy quark loop part of the gluon self-energy changes the running of the strong coupling constant $\alpha_s$, so that only light flavors contribute. Furthermore, we have explicitly shown how the commonly used effective renormalization formula for the coupling constant sums up all the counterterms, except for the one connected to mass renormalization. So mass renormalization has to be performed separately. Our treatment of the real contributions has been expounded in the next chapter. Since we have used the HVBM scheme [54] for extending $\gamma_5$ and $\epsilon_{\mu\nu\rho\sigma}$ to $n$-dimensions, we first had to generalize the $n$-dimensional $2 \to 3$ phase space integration by deriving an integral operator for the ensuing $\varepsilon$-dimensional "hat-space" terms.

In addition, we have created a program which automatically rewrites the phase space integration over the six different angular Mandelstam variables as a sum of basic angular integrals. Extensive partial fractioning is needed for this and we have explained the procedure in detail. We have also recalculated the needed basic angular integrals [44].
here, explaining how “tricks” can be used to reduce their number considerably. Most of the integrals have been extended to $O(\varepsilon)$, which may prove useful for future calculations. Finally, we have demonstrated in this chapter how phase space slicing isolates the soft real singularities, so that they can be canceled analytically against the infrared virtual ones.

Mass factorization is another topic which is seldomly explored in detail. So in Chap. 6 we have bridged the gap between the general formulae and the practical prescriptions by exhibiting the factorization of collinear singularities for one of our subprocesses. This also enables us to derive the LO renormalization group equations. Naturally we have compiled the other needed factorization formulae as well. In the next chapter we have calculated the other subprocesses. In each case we have shown the needed set of Feynman diagrams and the final parton level results. In order to facilitate comparisons with our calculation, we have displayed the total partonic cross sections for each of the subprocesses. Furthermore we have analyzed the properties of these partonic cross sections, in particular their spin dependence and size at threshold and at high energies.

We have checked our unpolarized results either analytically (for the virtual plus “soft” real part) or numerically (for the “hard” real part) against previous unpolarized calculations [44, 45, 46]. Also the “abelian” parts of $\gamma\gamma \to Q^\ast$ have been compared with the polarized and unpolarized NLO results for $\gamma\gamma \to Q$ [60]. Finally, we have checked each subprocess separately against the almost completely independent calculation of Dr. M. Stratmann: First, the matrix elements have been compared analytically. Second, the agreement after integration (loop and phase space, respectively), has been tested. Third, the programs for the partonic cross sections (and later for the hadron level predictions) give the same results. The Fortran source code of our photoproduction program, which includes a simple script based user interface for future use by other people, is about 100 KByte long. Considerable time has been spent on testing the program, for example by re-inserting all the programmed Fortran partonic cross sections into Mathematica and comparing them with the original results1.

The final chapter then considers the hadron level and the main points already have been discussed above. In the appendices we have collected some technical material. In particular App. B contains additional topics of general interest, for example the automatic calculation of color factors. To sum up, we have presented NLO QCD calculations that will be used to interpret experimental results very soon. It is probable that our knowledge about the polarized gluon distribution $\Delta g$, and thus of the spin of the nucleon, will be improved considerably by the experimental measurements and their theoretical analysis in NLO QCD.

1Very recently a second calculation of the complete NLO QCD corrections to polarized photoproduction has been finished [121]. Their virtual, soft, and collinear contributions are in full agreement [121]. However, in numerical comparisons at the hadron level differences of a few percent are seen [121]. In order to pin down the origin of these minor discrepancies, we hope that the authors of [121] will publish details about their parton level results and about comparisons of their unpolarized results to previous unpolarized calculations.
Appendix A

Additional Material Concerning Virtual Corrections

A.1 General Formula for Virtual Integrals

The integrals of the type (3.4) can be brought into the form

$$\mu^{4-n} \int \frac{d^3q}{(2\pi)^n} \frac{1}{(q^2 - K)^j}, \quad (A.1)$$

by introducing Feynman parameter integrals (3.7), i.e., (A.1) would have to be integrated with $J_j$. For example in the case of $D_0$ in the denominator one obtains with three Feynman parameters $x$, $y$, $z$ running from 0 to 1

$$a(q^2 - m_1^2 + i\epsilon) + b[(q + q_1)^2 - m_2^2 + i\epsilon] + c[(q + q_1 + q_2)^2 - m_3^2 + i\epsilon]$$

$$+ d[(q + q_1 + q_2 + q_3)^2 - m_4^2 + i\epsilon], \quad (A.2)$$

where the parameters $\{a, b, c, d\}$ are arbitrarily assigned to functions of the Feynman parameters: $\{1-x, x(1-y), xy(1-z), xyz\}$. Substituting

$$q \rightarrow q + bq_1 + c(q_1 + q_2) + d(q_1 + q_2 + q_3), \quad (A.3)$$

will bring (A.2) in the form $q^2 - K$ with $K$ as given in Tab. 3.1. Next we perform a Wick rotation on (A.1), rotating the energy component

$$q_0 \rightarrow ix_1, \quad q_{1,2,\ldots,n-1} \rightarrow x_{2,3,\ldots,n}, \quad (A.4)$$

to get an Euclidean integration. So the integral kernel is now $(-1)^j/(r^2 + K)^j$ with

$$r^2 \equiv x_1^2 + x_2^2 + \ldots + x_n^2, \quad (A.5)$$
and the integral measure is \(i d^n x\). Then we switch to \(n\)-dimensional spherical coordinates, by setting

\[
x_k = r \prod_{i=k}^{n-1} \sin \theta_i \cos \theta_{k-1},
\]

\[
x_1 = r \prod_{i=1}^{n-1} \sin \theta_i, \quad x_n = r \cos \theta_{n-1},
\]

with \(k = 1, \ldots, n\). The integration ranges are

\[
0 \leq r \leq \infty, \quad 0 \leq \theta_i \leq 2\pi \quad \text{and} \quad 0 \leq \theta_{k>1} \leq \pi.
\]

From the Jacobian we then get the integration measure \(r^{n-1} dr d\Omega_{n-1}\), with

\[
d\Omega_{n-1} = r^{n-1} \prod_{i=1}^{n-1} \sin^{i-1} \theta_i d\theta_i.
\]

So finally we have for (A.1)

\[
\mu^{4-n} (1)^j \int dr \frac{r^{n-1}}{(r^2 + K)^j} \int d\Omega_{n-1} \frac{(2\pi)^n}{(2\pi)^n}.
\]

Using

\[
\int_0^\pi d\theta \sin^m \theta = \frac{\sqrt{\pi} \Gamma \left(\frac{m+1}{2}\right)}{\Gamma \left(\frac{m+2}{2}\right)},
\]

we obtain for the angular integration \(2(16\pi^2)^{-n/4} / \Gamma \left(\frac{n}{2}\right)\) and the first integration corresponds to a beta function giving \(K^{n/2-j} B \left(\frac{n}{2}, \frac{n}{2}\right) / 2\). So the grand total is

\[
\frac{i \mu^{-\varepsilon}}{(16\pi^2)^{1+\varepsilon/4}} (1)^j K^{-j+2+\varepsilon/2} \Gamma (j-2-\frac{\varepsilon}{2}) \Gamma (j),
\]

where \(n = 4 + \varepsilon\) has been put in. Now we note that

\[
\frac{\Gamma \left(1-\frac{\varepsilon}{2}\right)}{(4\pi)^2} \left(\frac{4\pi \mu^2}{m^2}\right)^{-\varepsilon/2} = C_\varepsilon \left(1 + \frac{\varepsilon^2}{8} \zeta(2)\right) + O(\varepsilon^3),
\]

\[
\frac{\Gamma (j-2-\frac{\varepsilon}{2})}{\Gamma(1-\frac{\varepsilon}{2})} \frac{1}{\Gamma(j)} = \frac{1}{(j-2-\frac{\varepsilon}{2}) (j-1-\frac{\varepsilon}{2}) \Gamma(j) \Gamma \left(1-\frac{\varepsilon}{2}\right)}
\]

\[
1 - \frac{\varepsilon}{2} \sum_{k=1}^{j-1} \frac{1}{k} + \frac{\varepsilon^2}{8} \left[ \frac{j-1}{\sum_{k=1}^{j-1} \frac{1}{k}} + \sum_{k=1}^{j-1} \frac{1}{k^2} \right] + O(\varepsilon^3)
\]

\[
= \frac{1}{(j-2-\frac{\varepsilon}{2}) (j-1-\frac{\varepsilon}{2})},
\]

which directly leads to (3.5).
A.2 Calculation of Basic Scalar Integrals

In the following we will always use the formulae (3.5) to (3.7) and Tab. 3.1. The end results will be given up to $O(1$) and imaginary parts from the Feynman parameter integrals will be dropped, as explained in Sec. 3.2. The integrations are, if not mention otherwise, straightforward using standard integration tables like [82, 122] or programs like Mathematica [57]. The results are often only obtained after a fair amount of simplification using relations of higher transcendental functions, tabulated for example in [66, 122, 123]. Starting with the 1PF, we have $j = 1$, which directly gives the result

$$A_0(m) = i C_e m^2 \left( -\frac{2}{\varepsilon} + 1 \right),$$  

(A.13)

with $A_0(0) = 0$ in accordance with (3.3).

For the 2PF, with $j = 2$, we notice that the Feynman parameter integration itself cannot result in a pole. Thus we can use a series expansion in $\varepsilon$ there, when this simplifies the integration. However, due to the pole of $P_2(2)$, we need to expand up to $O(\varepsilon)$:

$$B_0(k_1, 0, 0) = i C_e \left( -\frac{2}{\varepsilon} \right) \int_0^1 dx 0^\frac{1}{2} = 0,$$  

(A.14)

$$B_0(k_1, m, m) = i C_e \left( -\frac{2}{\varepsilon} \right) \int_0^1 dx x^\frac{1}{2} = i C_e \left( -\frac{2}{\varepsilon} \right),$$  

(A.15)

$$B_0(p_1, 0, 0) = i C_e \left( -\frac{2}{\varepsilon} \right) \int_0^1 dx [-x(1-x)]^{\frac{1}{2}} = i C_e \left( -\frac{2}{\varepsilon} \right) (-1)^{\frac{1}{2}}$$

$$\cdot \left[ 1 + \frac{\varepsilon}{2} \int_0^1 dx \ln x + \ln(1-x) \right] = i C_e \left( -\frac{2}{\varepsilon} + 2 \right),$$  

(A.16)

$$B_0(p_1, 0, m) = i C_e \left( -\frac{2}{\varepsilon} \right) \int_0^1 dx x^{\frac{1}{2}} = i C_e \left( -\frac{2}{\varepsilon} + 2 \right),$$  

(A.17)

$$B_0(p_1 + p_2, 0, 0) = \left( \frac{s}{m^2} \right)^{\frac{1}{2}} B_0(p_1, 0, 0) = i C_e \left( -\frac{2}{\varepsilon} + 2 - \ln \frac{s}{m^2} \right),$$  

(A.18)

$$B_0(p_1 + p_2, m, m) = i C_e \left( -\frac{2}{\varepsilon} \right) \int_0^1 dx \left[ 1 - x(1-x) \frac{s}{m^2} \right]^{\frac{1}{2}} = i C_e \left( -\frac{2}{\varepsilon} \right)$$

$$\cdot \left[ 1 + \frac{\varepsilon}{2} \int_0^1 dx \left[ \ln(1 - (1+\varepsilon)x) + \ln \left( 1 - \frac{1+\varepsilon}{\varepsilon} x \right) \right] \right]$$

$$= i C_e \left( -\frac{2}{\varepsilon} + 2 + \beta \ln \varepsilon \right),$$  

(A.19)

$$B_0(p_1 - k_1, 0, m) = i C_e \left( -\frac{2}{\varepsilon} \right) \int_0^1 dx \left[ -\frac{t_1}{m^2} x(1 - \frac{t}{t_1} x) \right]^{\frac{1}{2}} = i C_e \left( -\frac{2}{\varepsilon} \right)$$

$$\cdot \left( -\frac{t_1}{m^2} \right) \left[ 1 + \frac{\varepsilon}{2} \int_0^1 dx \left[ \ln x + \ln \left( 1 - \frac{t}{t_1} x \right) \right] \right]$$
\[ -iC_\varepsilon \left[ -\frac{2}{\varepsilon} + 2 - \frac{t_1}{t} \ln \left( -\frac{t_1}{m^2} \right) \right], \]  

(A.20)

where \( \beta \equiv \sqrt{1 - 4m^2/s} \) and \( \varkappa \equiv (1 - \beta)/(1 + \beta) \).

For \( j = 3 \), we begin with three finite 3PF integrals. The \( C_0(p_1, -k_1, 0, m, m) \) kernel can be written as \( K = x \left[ x - (1 - x) y \frac{4m^2}{(1 + \varkappa)^2} \right] \), which is raised to the power \(-1 + \varepsilon/2\). With the additional \( x \) in the numerator from (3.7), we get a finite integral, which is evaluated easily upon setting \( \varepsilon \to 0 \):

\[ C_0(p_1, -k_1, 0, m, m) = iC_\varepsilon \frac{1}{s^2} \left[ \frac{1}{2} \ln^2 \varkappa - 3\zeta(2) \right]. \]  

(A.21)

Turning to \( C_0(-k_1, -k_2, m, m, m) \), the integral is obviously finite. With \( \varepsilon \to 0 \) and the parameters set so that \( K = \frac{1 - \beta^2 - 4(1-x)y}{1-x} \), the integral over \( y \) is simple and leads to an integration over \( \ln \left[ \frac{(1-x)^2 - \beta^2}{1-x} \right] \). Substituting \( z = 1 - 2x \) and integrating over \( z \) gives

\[ C_0(-k_1, -k_2, m, m, m) = iC_\varepsilon \frac{1}{s^2} \left[ \frac{1}{2} \ln^2 \varkappa - 3\zeta(2) \right]. \]  

(A.22)

Next \( C_0(p_1, p_2, 0, m, 0) \) is also obviously finite and after setting \( \varepsilon \to 0 \) most easily calculated by taking \( K = -x(1-x)(1-y)(1 + \varkappa)^2 + x^2 y \), which after integrating \( x \) leads to a term \( \ln \left[ \frac{(1-x)^2 - \beta^2}{1-x} \right] \), and the final result is

\[ C_0(p_1, p_2, 0, m, 0) = iC_\varepsilon \frac{1}{s^2} \left[ 2 \text{Li}_2(-\varkappa) + \frac{1}{2} \ln^2 \varkappa + \zeta(2) \right]. \]  

(A.23)

The integral \( C_0(p_2, p_1, m, 0, m) \) leads to \( K = -x^2 y (1-y) \frac{1}{m^2} + x^2 \). We thus get separate integrations for \( x \) and \( y \), with the \( x \) integration simply giving a pole \( 1/\varepsilon \). The left over \( y \) integration is finite and so we can expand up to \( O(1) \), getting a remaining integration over \( (\frac{1}{\varepsilon} + \ln r)/r \) with \( r \equiv (1 + \varkappa)y(1 - \frac{1 + \varkappa}{m^2} y) \). So in the end

\[ C_0(p_2, p_1, m, 0, m) = iC_\varepsilon \frac{1}{s^2} \left[ -\frac{2}{\varepsilon} \ln \varkappa - 2 \ln \varkappa \ln(1 - \varkappa) - 2 \text{Li}_2(\varkappa) + \frac{1}{2} \ln^2 \varkappa - 4\zeta(2) \right]. \]  

(A.24)

\( C(-k_1, -k_2, 0, 0, 0) \) is a very simple integral, since with \( K = -xy(1-x) \frac{1}{m^2} \) one finds again two separate integrations. The one over \( y \) directly gives \( 2/\varepsilon \) and the one over \( x \) corresponds to a beta function \( B(1 + \frac{5}{2}, \frac{7}{2}) \), so that the series expansion in \( \varepsilon \) is

\[ C_0(-k_1, -k_2, 0, 0, 0) = iC_\varepsilon \frac{1}{s^2} \left[ \frac{4}{\varepsilon^2} + \frac{2}{\varepsilon} \ln \frac{s}{m^2} + \frac{1}{2} \ln \ln \frac{s}{m^2} - \frac{7}{2} \zeta(2) \right]. \]  

(A.25)

Finally \( C_0(-k_1, p_1, 0, 0, m) \) can be directly integrated to a double pole and a hypergeometric function using \( K = (1 - x) \left[ xy \left( -\frac{1}{m^2} \right) + 1 - x \right] \) and with the appropriate expansion
for the hypergeometric function (B.6) the result
\[
C_0(-k_1, p_1, 0, 0, m) = \left( \frac{2}{\varepsilon^2} + \frac{2}{\varepsilon} \ln \left( -\frac{t_1}{m^2} \right) + \ln^2 \left( -\frac{t_1}{m^2} \right) + \text{Li}_2 \left( \frac{t}{m^2} \right) + \frac{\zeta(2)}{4} \right),
\]
(A.26)
is obtained. This completes the set of needed 3PFs.

Turning to the box integrals, the calculation of
\[
D_0(-k_1, p_1, 0, 0, m, 0) = \frac{iC_e}{s t_1} \left[ \frac{8}{\varepsilon^2} + \frac{2}{\varepsilon} \left( 2 \ln \tilde{t} + \ln \tilde{s} \right) + 2 \ln \tilde{s} \ln \tilde{t} - 4 \zeta(2) \right],
\]
(A.27)
is shown in Sec. 3.2. The second 4PF needed is \(D_0(-k_1, p_1, -k_2, 0, 0, m, m)\). The kernel can be chosen as \(K = xyz \{ x[\tilde{t} - (\tilde{t} - 1)y] + [\tilde{u}(1 - x) - \tilde{t}x(1 - y)]z \} \), with \(\tilde{t} \equiv -t_1/m^2\) and \(\tilde{u} \equiv -u_1/m^2\). We can integrate over \(x^2 y K^{-2+\varepsilon/2}\) with respect to \(z\) to get the result \(I_{xy} + II_{xy}\) with
\[
\frac{2x^{-1+\varepsilon}y^{-1+\varepsilon}z^{-1+\varepsilon}}{(-2 + \varepsilon) \tilde{u}(1 - x) - \tilde{t}x(1 - y)} + \frac{2x^{-1+\varepsilon}y^{-1+\varepsilon}z^{-1+\varepsilon}}{(-2 + \varepsilon) \tilde{u}(1 - x) - \tilde{t}x(1 - y)}.
\]
(A.28)
The integration of \(I_{xy}\) over \(x\) is straightforward:
\[
I_y = -\frac{2y^{-1+\varepsilon}z^{-1+\varepsilon}}{(-2 + \varepsilon) \tilde{u}} \cdot \frac{2F_1 \left( 1, \varepsilon, 1 + \varepsilon; \frac{\tilde{u} + \tilde{t}(1 - y)}{\tilde{u}} \right)}{1 - \varepsilon \ln \left( \frac{\tilde{u}}{\tilde{t}} \right) - \varepsilon^2 \text{Li}_2 \left( \frac{1 + \tilde{t}}{\tilde{u}} \right)}.
\]
(A.29)
The hypergeometric function can be expanded, see (B.5), and we define an appropriate counterterm for the diverging \(y \to 0\) limit
\[
I_y^\varepsilon = -\frac{2y^{-1+\varepsilon}z^{-1+\varepsilon}}{(-2 + \varepsilon) \tilde{u}} \left[ 1 - \varepsilon \ln \left( \frac{\tilde{u}}{\tilde{t}} \right) - \varepsilon^2 \text{Li}_2 \left( \frac{1 + \tilde{t}}{\tilde{u}} \right) \right] .
\]
(A.30)
Integration of the counterterm and adding the integration of the expansion of \(I_y - I_y^\varepsilon\) leads to
\[
I = \frac{1}{\tilde{t} \tilde{u}} \left[ \frac{2}{\varepsilon^2} + \frac{1}{\varepsilon} + \frac{1}{2} + \frac{\pi^2}{6} - \ln^2 \tilde{t} + \ln \tilde{u} + 2 \ln \tilde{s} \ln \tilde{u} - 2 \text{Li}_2 \left( 1 + \frac{\tilde{t}}{\tilde{u}} \right) \right] .
\]
(A.31)

Turning to \(II_{xy}\) we can expand \(x^{\varepsilon/2}\) because the integral over \(x\) does not diverge for \(x \to 0\). Starting with order one, \(x^{\varepsilon/2} \to 1\), we get
\[
II_{xy}^{(1)} = -\frac{4\tilde{u}^{-1+\varepsilon}y^{-1+\varepsilon}z^{-1+\varepsilon} \tilde{t} - (\tilde{t} - 1)y]^{-1+\varepsilon} \tilde{u} - y^{-1+\varepsilon}}{(-2 + \varepsilon) \tilde{u}} \left\{ -i\varepsilon \pi \eta^{-1+\varepsilon} + \left[ (-1)^{-1+\varepsilon} \right] \cdot 2F_1 \left( \frac{\eta}{2}, \frac{1 + \eta}{2}; \frac{\tilde{u}}{2}; -\frac{\tilde{u} \eta}{\tilde{t}(1 - y)} \right) \right\} ,
\]
(A.32)
with $\eta \equiv \frac{i + \tilde{u} - i_{y}}{\eta - y}$. We use again (B.6) and the $y \to 0$ counterterm is

$$II^{(1)}_{y} = -\frac{4\tilde{u}^{-1+\frac{7}{2}} y^{-1+\frac{7}{2}} \tilde{t}^{-1+\frac{7}{2}}}{(2+\varepsilon)\varepsilon} \left\{ -i\varepsilon \pi (\tilde{t} + \tilde{u})^{-\frac{7}{2}} + \tilde{u}^{-\frac{7}{2}} \cdot \left( -1 \right)^{\frac{7}{2}} \left( 1 + \frac{\varepsilon^{2}}{4} \text{Li}_{2} \left( 1 + \frac{\tilde{t}}{\tilde{u}} \right) \right) - \tilde{t}^{-\frac{7}{2}} y^{\frac{7}{2}} \right\}. \quad (A.33)$$

This again enables us to calculate $II^{(1)}$. But there is also the next order of $x^{\varepsilon/2}$ to consider, with $x^{\varepsilon/2} \to \frac{x}{2} \ln x$ in $II_{xy}$. Since for $y \to 0$ there is no divergence for $x \to 1$ because of the $\ln x$, and since the $y$-integration can only deliver a $1/\varepsilon$-pole, this is also the last order we have to consider. Furthermore we can set $\varepsilon \to 0$ in $[\tilde{u}(1-x)+xy]^{-1+\varepsilon/2}$ for the same reason and the only term that contributes after partial fractioning is

$$I^{(1)}_{xy} = \frac{\varepsilon y^{-1+\frac{7}{2}} \ln x}{(2+\varepsilon)(\tilde{u}(1-x) - \tilde{t}x)(1-x)\tilde{u}}, \quad (A.34)$$

which can be easily integrated. So the sum becomes

$$II = \frac{1}{\tilde{u}} \left[ \frac{2}{\varepsilon^{2}} + \frac{1+2\ln \tilde{t}}{\varepsilon} + \frac{1}{2} - \frac{5\pi^{2}}{6} + \ln \tilde{t} + \ln^{2} \tilde{t} + 2 \text{Li}_{2} \left( 1 + \frac{\tilde{t}}{\tilde{u}} \right) \right], \quad (A.35)$$

and we obtain the final result

$$D_{0}(k_{1}, p_{1}, -k_{2}, 0, 0, m, m) = \frac{iC_{e}}{t_{1}u_{1}} \left\{ \frac{4}{\varepsilon^{2}} + \frac{2}{\varepsilon} \left[ \ln \tilde{t} + \ln \tilde{u} \right] + 2 \ln \tilde{t} \ln \tilde{u} - \frac{7\zeta(2)}{2} \right\}. \quad (A.36)$$

The last box integral needed is $D_{0}(p_{1}, -k_{1}, -k_{2}, 0, m, m, m)$. We can write the kernel as $K = \frac{2}{\varepsilon} \left\{ x \left[ x - (1+x)^{2}(1-y)y \right] + \left[ \lambda \tilde{t}(1-x) + (1+x)^{2}x(1-y) \right] y^{\frac{7}{2}} \right\}$, so we get for the $z$-integration $I_{xy} + II_{xy}$, with

$$I_{xy} = \frac{2\pi x^{-\frac{7}{2}} \left( x + \tilde{t}(1-x)y \right)^{-1+\frac{7}{2}}}{(2+\varepsilon) \left[ x + (1+x)^{2}(1-y)y \right]}, \quad (A.37)$$

$$II_{xy} = -\frac{2\pi x^{-\frac{7}{2}} x^{-1+\varepsilon} \left[ x - (1+x)^{2}(1-y)y \right]^{-1+\frac{7}{2}}}{(2+\varepsilon) \left[ x + \lambda \tilde{t}(1-x) + (1+x)^{2}x \right]}. \quad (A.37)$$

The integration of $I_{xy}$ does not diverge and one easily gets upon setting $\varepsilon \to 0$

$$I = \frac{m^{4}}{\beta s t_{1}} \left[ \ln^{2} \pi + 4 \text{Li}_{2}(-\pi) + \frac{\pi^{2}}{3} \right]. \quad (A.38)$$

Integrating $II_{xy}$ over $x$ gives

$$II_{y} = -\frac{2\pi^{-\frac{7}{2}} \left[ x - (1+x)^{2}(1-y)y \right]^{-1+\frac{7}{2}} \text{F} \left( 1, \frac{1+\tilde{t}}{\tilde{u}} \right)}{(2+\varepsilon)\varepsilon \tilde{t}}. \quad (A.39)$$
The integration over $y$ does not give an additional pole, so we can expand to $O(1)$ using (B.5) and then integrate to obtain

$$II = -\frac{m^4}{\beta st_1} \left\{ \frac{2 \ln \varepsilon}{\varepsilon} + \ln \varepsilon \left[ 1 + 2 \ln \beta + \ln \varepsilon + 2 \ln \tilde{t} \right] + \text{Li}_2 \left( \varepsilon^2 \right) + \frac{5\pi^2}{6} \right\}. \quad (A.40)$$

The final result is then

$$D_0(p_1, -k_1, -k_2, 0, m, m, m)$$

$$= -\frac{i C}{\beta st_1} \left\{ \frac{2 \ln \varepsilon}{\varepsilon} + 2 \left[ \ln \varepsilon \ln(\beta \tilde{t}) - \text{Li}_2(-\varepsilon) + \text{Li}_2(\varepsilon) \right] + 3\zeta(2) \right\}. \quad (A.41)$$

This recalculation of the needed basic scalar integrals is in complete agreement with the results presented in [44].

## A.3 Passarino-Veltman Decomposition

In Sec. 3.3 the necessary projection mechanisms for the decomposition of the tensor integrals was constructed. Here we list the obtained formulae. Auxiliary coefficients are named like in [67], to facilitate comparisons. Two additional relations as compared to [67] will be derived to complete the consistency checks, i.e., for every coefficient that can be obtained in more than one way at least two equations are given. Of course, all consistency checks were successful. The notation for scalar integrals used here follows the conventions employed in Sec. 3.3: Any non-standard product of propagators in integrals of the form (3.4) is indicated by listing the numbers $i$ of the propagator functions $L_i$ in brackets. From (3.4) we have as standard 2PF and 3PF $B_0 = B_0(1,2)$ and $C_0 = C_0(1,2,3)$, respectively. Naturally there is only one 1PF $A_0 = A_0(1) = A_0(2) = A_0(3) = A_0(4)$, since we can always redefine the loop momentum. Furthermore, there are only four external particles in our (virtual) subprocesses, so the standard $D_0 = D_0(1,2,3,4)$ is the only 4PF that occurs here. There is one non-standard 2PF: $B_0(2,3)$, see (3.27), and there are three non-standard 3PFs: $C_0(1,2,4)$, $C_0(1,3,4)$, and $C_0(2,3,4)$. The first two can be found in the example given in (3.19) and $C_0(2,3,4)$ then corresponds to

$$C_0(2,3,4) = \mu^{-\varepsilon} \int \frac{d^n q}{(2\pi)^n} \frac{1}{\left[ (q + q_1)^2 - m_2^2 \right] \left[ (q + q_1 + q_2)^2 - m_3^2 \right] \left[ (q + q_1 + q_2 + q_3)^2 - m_4^2 \right]} \quad (A.42)$$

The tensor 2PF coefficients are

$$B_1 = \frac{1}{2q_1^2} \left[ f_1 B_0 + A_0(m_1) - A_0(m_2) \right], \quad (A.43)$$

$$B_{21} = \frac{1}{q_1^2} \left\{ \frac{1}{2} \left[ f_1 B_1 + A_0(m_2) \right] - B_{22} \right\}. \quad (A.44)$$
Table A.1: The Passarino-Veltman matrix coefficients of the 3PFs, to be inserted in (A.47). The $R_i$ are shown in (A.48).

\[
B_{22} = \frac{1}{n-1} \left\{ m_1^2 B_0 - \frac{1}{2}[f_1 B_1 - A_0(m_2)] \right\}. \tag{A.45}
\]

For the 3PFs we have one scalar equation

\[
C_{24} = \frac{1}{n-2}[B_0(2, 3) + m_2^2 C_0 - R_3 - R_6], \tag{A.46}
\]

and the $R_i$ are given in (A.48) below. The rest is in matrix form

\[
\begin{pmatrix}
C_a \\
C_b
\end{pmatrix} = X_C^{-1}
\begin{pmatrix}
M_a \\
M_b
\end{pmatrix}, \tag{A.47}
\]

and the combinations are presented in Tab. A.1.

The $R$-coefficients of the 3PFs are

\[
\begin{align*}
R_1 &= \frac{1}{2}[f_1 C_0 + B_0(1, 3) - B_0(2, 3)], & R_2 &= \frac{1}{2}[f_2 C_0 + B_0(1, 2) - B_0(1, 3)], \\
R_3 &= \frac{1}{2}[f_1 C_{11} + B_1(1, 3) + B_0(2, 3)], & R_4 &= \frac{1}{2}[f_2 C_{11} + B_1(1, 2) - B_1(1, 3)], \\
R_5 &= \frac{1}{2}[f_1 C_{12} + B_1(1, 3) - B_1(2, 3)], & R_6 &= \frac{1}{2}[f_2 C_{12} - B_1(1, 3)], \\
R_{10} &= \frac{1}{2}[f_1 C_{24} + B_{22}(1, 3) - B_{22}(2, 3)], & R_{11} &= \frac{1}{2}[f_2 C_{24} + B_{22}(1, 2) - B_{22}(1, 3)], \\
R_{12} &= \frac{1}{2}[f_1 C_{21} + B_{21}(1, 3) - B_0(2, 3)], & R_{13} &= \frac{1}{2}[f_2 C_{21} + B_{21}(1, 2) - B_{21}(1, 3)], \\
R_{14} &= \frac{1}{2}[f_1 C_{22} + B_{21}(1, 3) - B_{21}(2, 3)], & R_{15} &= \frac{1}{2}[f_2 C_{22} - B_{21}(1, 3)],
\end{align*}
\]
Table A.2: The Passarino-Veltman matrix coefficients of the 4PFs, to be inserted in (A.50). The $R_i$ are shown in (A.51). The last two rows show results that complete the set of consistency checks.

\[
R_{i6} = \frac{1}{2} [f_1 C_{23} + B_{21}(1,3) + B_{1}(2,3)], \quad R_{i7} = \frac{1}{2} [f_2 C_{23} - B_{21}(1,3)]. \tag{A.48}
\]

In the 4PFs we also have only one scalar equation

\[
D_{27} = \frac{1}{n - 3} [C_0(2,3,4) + m_1^2 D_0 - R_{30} - R_{34} - R_{38}], \tag{A.49}
\]

and the $R_i$ can be found in (A.51) below. The rest is again in matrix form

\[
\begin{pmatrix}
D_a \\
D_b \\
D_c
\end{pmatrix}
= X_D^{-1}
\begin{pmatrix}
M_a \\
M_b \\
M_c
\end{pmatrix}, \tag{A.50}
\]

and the combinations are presented in Tab. A.2. The $R$-coefficients of the 4PFs are

\[
\begin{align*}
R_{20} &= \frac{1}{2} [f_1 D_0 + C_0(1,3,4) - C_0(2,3,4)], \\
R_{21} &= \frac{1}{2} [f_2 D_0 + C_0(1,2,4) - C_0(1,3,4)], \\
R_{22} &= \frac{1}{2} [f_3 D_0 + C_0(1,2,3) - C_0(1,2,4)], \\
R_{30} &= \frac{1}{2} [f_1 D_{11} + C_{11}(1,3,4) + C_0(2,3,4)].
\end{align*}
\]
\[ R_{31} = \frac{1}{2} [f_2 D_{11} + C_{11}(1, 2, 4) - C_{11}(1, 3, 4)], \quad R_{32} = \frac{1}{2} [f_3 D_{11} + C_{11}(1, 2, 3) - C_{11}(1, 2, 4)], \]
\[ R_{33} = \frac{1}{2} [f_1 D_{12} + C_{11}(1, 3, 4) - C_{11}(2, 3, 4)], \quad R_{34} = \frac{1}{2} [f_2 D_{12} + C_{12}(1, 2, 4) - C_{11}(1, 3, 4)], \]
\[ R_{35} = \frac{1}{2} [f_3 D_{12} + C_{12}(1, 2, 3) - C_{12}(1, 2, 4)], \quad R_{36} = \frac{1}{2} [f_1 D_{13} + C_{12}(1, 3, 4) - C_{12}(2, 3, 4)], \]
\[ R_{37} = \frac{1}{2} [f_2 D_{13} + C_{12}(1, 2, 4) - C_{12}(1, 3, 4)], \quad R_{38} = \frac{1}{2} [f_3 D_{13} - C_{12}(1, 2, 4)], \]
\[ R_{39} = \frac{1}{2} [f_1 D_{27} + C_{24}(1, 3, 4) - C_{24}(2, 3, 4)], \quad R_{41} = \frac{1}{2} [f_2 D_{27} + C_{24}(1, 2, 4) - C_{24}(1, 3, 4)], \]
\[ R_{42} = \frac{1}{2} [f_3 D_{27} + C_{24}(1, 2, 3) - C_{24}(1, 2, 4)], \quad R_{43} = \frac{1}{2} [f_1 D_{21} + C_{21}(1, 3, 4) - C_{0}(2, 3, 4)], \]
\[ R_{44} = \frac{1}{2} [f_2 D_{21} + C_{21}(1, 2, 4) - C_{21}(1, 3, 4)], \quad R_{45} = \frac{1}{2} [f_3 D_{21} + C_{21}(1, 2, 3) - C_{21}(1, 2, 4)], \]
\[ R_{46} = \frac{1}{2} [f_1 D_{22} + C_{21}(1, 3, 4) - C_{21}(2, 3, 4)], \quad R_{47} = \frac{1}{2} [f_2 D_{22} + C_{22}(1, 2, 4) - C_{21}(1, 3, 4)], \]
\[ R_{48} = \frac{1}{2} [f_3 D_{22} + C_{22}(1, 2, 3) - C_{22}(1, 2, 4)], \quad R_{49} = \frac{1}{2} [f_1 D_{23} + C_{22}(1, 3, 4) - C_{22}(2, 3, 4)], \]
\[ R_{50} = \frac{1}{2} [f_2 D_{23} + C_{22}(1, 2, 4) - C_{22}(1, 3, 4)], \quad R_{51} = \frac{1}{2} [f_3 D_{23} - C_{22}(1, 2, 4)], \]
\[ R_{52} = \frac{1}{2} [f_1 D_{24} + C_{21}(1, 3, 4) + C_{11}(2, 3, 4)], \quad R_{53} = \frac{1}{2} [f_2 D_{24} + C_{23}(1, 2, 4) - C_{21}(1, 3, 4)], \]
\[ R_{54} = \frac{1}{2} [f_3 D_{24} + C_{23}(1, 2, 3) - C_{23}(1, 2, 4)], \quad R_{55} = \frac{1}{2} [f_1 D_{25} + C_{23}(1, 3, 4) + C_{12}(2, 3, 4)], \]
\[ R_{56} = \frac{1}{2} [f_2 D_{25} + C_{23}(1, 2, 4) - C_{23}(1, 3, 4)], \quad R_{57} = \frac{1}{2} [f_3 D_{25} - C_{23}(1, 2, 4)], \]
\[ R_{58} = \frac{1}{2} [f_1 D_{26} + C_{23}(1, 3, 4) - C_{23}(2, 3, 4)], \quad R_{59} = \frac{1}{2} [f_2 D_{26} + C_{22}(1, 2, 4) - C_{23}(1, 3, 4)], \]
\[ R_{51} = \frac{1}{2} [f_3 D_{26} - C_{22}(1, 2, 4)]. \] (A.51)
Appendix B

Some Technical Issues

B.1 Series Expansion of Hypergeometric Functions

In the calculation of integrals in dimensional regularization one often obtains hypergeometric functions $\mathbf{2} \mathrm{F}_1(a, b, c; z)$, in which the parameters $a$, $b$ and $c$ depend on the "hat space" dimension parameter $\varepsilon$. This is due to integrals having forms similar to

$$
\mathbf{2} \mathrm{F}_1(a, b, c; z) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(c - b)} \int_0^1 dt \frac{t^{b-1}(1 - t)^{c-b-1}}{(1 - tz)^a} \quad \text{for} \quad \text{Re}(c) > \text{Re}(b) > 0 .
$$

(B.1)

A straightforward evaluation or even worse further integration of the hypergeometric function for non-integer values of $a, b, c$ is usually not feasible. On the other hand a series expansion in $\varepsilon$ of these functions is sufficient, if we can obtain the appropriate order. In our calculations the strongest poles are $\mathcal{O}(1/\varepsilon^2)$, so that at most a series expansion to $\mathcal{O}(\varepsilon^2)$ is necessary. There are a few expansions collected in the literature, for example in [65], but we have found no comment on how they were obtained. The following efficient method may have been too simple to be mentioned explicitly.

The hypergeometric functions are solutions of the following differential equation and boundary condition:

$$
z(1 - z)w''(z) + [c - (a + b + 1)z]w'(z) - abw(z) = 0 \quad \text{with} \quad w(0) = 1 ,
$$

(B.2)

in which the derivative is with respect to $z$. Now we simply set for finite\footnote{One can always use linear transformations of $\mathbf{2} \mathrm{F}_1$ to move a $\varepsilon \to 0$ divergence in $a, b, c$ out of the hypergeometric function.} $\mathbf{2} \mathrm{F}_1$

$$
w(z) = r(z) + \varepsilon s(z) + \varepsilon^2 t(z) + \ldots
$$

(B.3)

In our case the first three terms are sufficient. By inserting (B.3) and the $\varepsilon$-dependent values of $a$, $b$ and $c$ in (B.2) and expanding the differential equation in $\varepsilon$, we obtain a system of simpler differential equations, since each coefficient of the powers of $\varepsilon$ has to be
zero. These equations are coupled, but since the parameters $a$, $b$ and $c$ have no poles in $\varepsilon$, we can proceed step by step: first at $O(1)$ we can obtain $r(z)$, which is then inserted in the $O(\varepsilon)$ differential equation to get $s(z)$ and so on. Furthermore (B.2) means that we get the boundary conditions $r(0) = 1$ and $s(z) = t(z) = \ldots = 0$.

An example should make this clear, $2F_1(1, \varepsilon, 1 + \varepsilon; z)$ leads to the following set of differential equations:

\[
\begin{align*}
O(1) \quad \Rightarrow \quad & (1 - 2z)r' + (1 - z)rr'' = 0 \\
O(\varepsilon) \quad \Rightarrow \quad & -r' + (1 - z)r' + (1 - 2z)s' + (1 - z)zs'' = 0 \\
O(\varepsilon^2) \quad \Rightarrow \quad & -s + (1 - z)s' + (1 - 2z)t' + (1 - z)zt'' = 0.
\end{align*}
\]

Solving the $O(1)$ part with $r(0) = 1$ yields $r(z) = 1$. This we can put in the $O(\varepsilon)$ part and using $s(z) = 0$ we have $s(z) = -\ln(1 - z)$. Finally inserting $r(z)$ and $s(z)$ into the $O(\varepsilon^2)$ equation with $t(0) = 0$ leads to $t(z) = -\text{Li}_2(z)$. Putting all together we have

\[
2F_1(1, \varepsilon, 1 + \varepsilon; z) = 1 - \varepsilon \ln(1 - z) - \varepsilon^2 \text{Li}_2(z) + O(\varepsilon^3).
\]

Other needed hypergeometric functions, which can be easily obtained using this method, are

\[
\begin{align*}
2F_1(1, -\varepsilon, 1 + \varepsilon; z) &= 1 + \varepsilon \ln(1 - z) + \varepsilon^2 \left[\ln^2(1 - z) + \text{Li}_2(z)\right] + O(\varepsilon^3), \\
2F_1(\varepsilon, 1 + \varepsilon, 2 + \varepsilon; z) &= 1 - \varepsilon \left[1 + \frac{1}{z} \ln(1 - z)\right] + O(\varepsilon^2), \\
2F_1(\varepsilon, \pm \varepsilon, 1 + \varepsilon; z) &= 1 \pm \varepsilon^2 \text{Li}_2(z) + O(\varepsilon^3), \\
2F_1(1 + \varepsilon, 2 + \varepsilon; z) &= -\frac{\ln(1 - z)}{z} - \frac{1}{z} \ln(1 - z) + \text{Li}_2(z) + O(\varepsilon^3).
\end{align*}
\]

Sometimes it is simpler to use the differentiation properties of the hypergeometric function directly. For example using the above method it is straightforward to obtain

\[
2F_1\left(1, 1 + \frac{\varepsilon}{2}, 2 + \varepsilon; z\right) = -\frac{\ln(1 - z)}{z} - \frac{1}{z} \ln(1 - z) + \frac{1}{4} \ln^2(1 - z) + \text{Li}_2(z) + O(\varepsilon^3).
\]

But it becomes increasingly difficult to solve $2F_1\left(1, 1 + \frac{\varepsilon}{2}, 2 + \varepsilon + k; z\right)$ for growing $k$. Instead one can employ the formula

\[
\frac{\partial^k}{\partial z^k} ((1 - z)^{a+b-c} 2F_1(a, b, c; z)) = \frac{(c-a)_{k}(c-b)_{k}}{(c)_{k}} (1 - z)^{a+b-c-k} 2F_1(a, b, c + k; z),
\]

where $(x)_k \equiv \Gamma(x + k)/\Gamma(x)$ is the Pochhammer symbol. Since the differentiation with respect to $z$ of (B.7) is simple, we can quickly obtain the needed results. There are several differentiation formulae to be found in the literature, see for example [66].
B.2 Dilogarithmic and Logarithmic Branch Cuts

The dilogarithm $\text{Li}_2$ is defined by

$$\text{Li}_2(x) \equiv -\int_0^1 dy \frac{\ln(1 - yx)}{y} = -\int_0^x dy \frac{\ln(1 - y)}{y}. \quad (B.9)$$

We use the common prescription for the branch cut of the complex logarithm, i.e., we place it along the negative real axis from 0 to $-\infty$. That means for real $x$

$$\ln(x \pm i\epsilon) = \ln |x| \pm i\pi \Theta(-x),$$

$$\lim_{\epsilon \to 0^+} [\ln(x + i\epsilon) - \ln(x - i\epsilon)] \equiv 2i\pi. \quad (B.10)$$

So by using (B.9) we find for the discontinuity of the dilogarithm

$$\lim_{\epsilon \to 0^+} [\text{Li}_2(x + i\epsilon) - \text{Li}_2(x - i\epsilon)] \equiv 2i\pi \ln x, \quad (B.11)$$

at the branch cut extending from 1 to $\infty$ on the real axis.

One often uses relations like the following [122] for the transformation of the dilogarithms:

$$\text{Li}_2(y) + \text{Li}_2(1 - y) = -\ln(y) \ln(1 - y) + \zeta(2),$$

$$\text{Li}_2(y) + \text{Li}_2\left(\frac{1}{y}\right) = -\frac{1}{2} \ln^2(-y) - \zeta(2),$$

$$\text{Li}_2(y) - \text{Li}_2\left(\frac{y - 1}{y}\right) = -\ln(y) \ln(1 - y) + \frac{1}{2} \ln^2(y) + \zeta(2), \quad (B.12)$$

$$\text{Li}_2(y) + \text{Li}_2\left(\frac{y}{y - 1}\right) = -\frac{1}{2} \ln^2(1 - y),$$

$$\text{Li}_2(y) + \text{Li}_2(-y) = \frac{1}{2} \text{Li}_2(y^2).$$

So if we have arguments which are slightly shifted to the imaginary, in order to stay away from the (di)logarithmic branch cuts, in principle we would have to carefully consider to which side we have shifted, see (B.11). But as explained in Sec. 3.2, we can drop all purely imaginary parts anyway. Since the dilogarithms only occur linearly with real coefficients, we can actually ignore the problems completely for the dilogarithms and just compute their real parts.

On the other hand logarithms do occur squared or with partly imaginary coefficients, so we have to use (B.10), or we will not be able to correctly calculate the $\pi^2$-terms of the integrals. An efficient way of proceeding is to simply calculate with the kernels $K$ of Tab. 3.1 as if the causal $i\epsilon$ was not there. Then in the end logarithms occur which have arguments on the branch cut. We can now treat the original kinematic invariants occurring in the logarithms as if they had small positive imaginary parts. For example,
we find in the kernel the term $\ldots - a c (q_1 + q_2)^2 / m^2 + \ldots - i \varepsilon$. Say $q_1 = k_1$ and $q_2 = k_2$, then $(q_1 + q_2)^2 = s$. Now $a$, $c$, $m$ are positive and we can consider $s$ to have a small positive imaginary part in order to preserve the correct shift away from the branch cut, e.g.,

$$\ln \left( -\frac{s}{m^2} \right) \rightarrow \ln \left( -\frac{s + i \varepsilon m^2}{m^2} \right) = \ln \left( \frac{s}{m^2} \right) - i \pi .$$

(B.13)

In cases where the argument of the logarithm is a complicated function of the original variable, we can perform a series expansion of it in $\varepsilon$, e.g.,

$$\ln \left( -\frac{x}{1 - x} \right) \rightarrow \ln \left( -\frac{x}{1 - x} + i \varepsilon \frac{m^4}{s^2 \beta^3} \right) = \ln(x) - \ln(1 - x) + i\pi,$$

(B.14)

where $\alpha = (1 - \beta) / (1 + \beta)$ and $\beta = \sqrt{1 - 4m^2 / s}$. Using these methods one arrives at the correct real parts of the integrals, which are needed exclusively here.

### B.3 Calculation of $SU(N)$ Color-Factors

![Diagram](image)

(a) $f^{ae} f^{bce} \text{Tr} \left< T^a T^d T^j T^b \right>$

(b) $f^{aik} f^{abc} \text{Tr} \left< T^i T^j T^k \right> \text{Tr} \left< T^d T^e \right>$

Figure B.1: Contributions to the real (a) and the virtual (b) NLO squared matrix element occurring in hadroproduction are used to illustrate the pairing of all occurring color indices.

In calculating a cross section, one obviously has to sum over all the color degrees of freedom of the internally exchanged particles. But since observable hadrons are “white”, i.e., carry no color, there is no information at all on the color of their (unobserved) partons. These partons enter as external particles in the partonic subprocess, so one also has to sum over all their colors. Thus all color indices are summed over in the partonic subprocess. Furthermore as Fig. B.1 indicates, the Feynman rules will always result in paired color indices for the squared matrix elements. The external particles have to match in color to be coherently added and the internal particles couple at two points. We will see below, that then for every squared QCD matrix element one finds that the color structure of the particles is reduced to a number which multiplies a colorless squared matrix element similar to what one gets in a QED calculation. These numbers are called color-factors and

---

2To obtain a proper normalization one should average over the incoming color states, i.e., divide the sum over color indices of incoming partons by their total number of colors.
we can calculate them independently of the remaining colorless squared matrix elements.
Though the calculation is rather simple in principle, it quickly becomes tedious for the multiple color exchanges in higher orders. In the following an algorithm for calculating $SU(N)$ color factors is described which was inspired by the general ideas of [124].

First let us specify the notation for the $N^2 - 1$ independent $N \times N$-matrix generators, which yield the lowest-dimensional representation of the Lie algebra of $SU(N)$:

$$T^a_{ij} = \frac{1}{2} \lambda^a_{ij}, \quad \text{Tr} \langle T^a \rangle = 0, \quad \text{Tr} \langle T^a T^b \rangle = \frac{1}{2} \delta^{ab}, \quad (B.15)$$

$$[T^a, T^b] = i f^{abc} T^c, \quad \{T^a, T^b\} = \frac{1}{N} \delta^{ab} I_N + d^{abc} T^c. \quad (B.16)$$

Here and below the fundamental (“quark”) indices range over $i, j, \ldots = 1, 2, \ldots, N$ and are written as subscripts. In QCD, the quarks are in the fundamental representation of $SU(3)_{\text{color}}$. The fundamental representation has the dimension $N$, i.e., in QCD the quarks have $N = N_C = 3$ color states. The adjoint (“gluon”) indices range over $a, b, \ldots = 1, 2, \ldots, N^2 - 1$ and are written as superscripts. The gluons of QCD are in the adjoint representation of $SU(3)_{\text{color}}$. The adjoint representation has the dimension $N^2 - 1$, since a special unitary group has $N^2 - 1$ generators. Thus in QCD there are $N^2 - 1 = 8$ gluon color states. The structure constants $f^{abc}$ and $d^{abc}$ are totally antisymmetric and symmetric, respectively, under the interchange of any two indices. The $\lambda^a$ matrices correspond to those introduced by Clay-Mann [125] in the case of $SU(3)$. The notation is valid for $SU(N)$, but commonly used only for $SU(3)$. For $SU(2)$ the conventional notation is recovered by setting $(\lambda^a, f^{abc}, d^{abc}) \rightarrow (\sigma^a, e^{abc}, 0)$ with the Pauli matrices $\sigma^a$ and the Levi-Civita tensor $e^{abc}$.

The central relations employed in the automatic evaluation of color-factors are

$$T^a_{ij} T^a_{kl} = \frac{1}{2} \left[ \delta_{il} \delta_{jk} - \frac{1}{N} \delta_{ij} \delta_{kl} \right], \quad (B.17)$$

$$f^{abc} = -2i \text{Tr} \langle T^a [T^b, T^c] \rangle, \quad d^{abc} = 2 \text{Tr} \langle T^a \{T^b, T^c\} \rangle. \quad (B.18)$$

Any structure constants appearing$^3$ can be turned into strings of generators using the trace relations with the (anti)commutator of generators in (B.18). Since all “gluon” color indices come in pairs, relation (B.17) is sufficient to reduce the corresponding collection of generators into $\delta$-functions of “quark” indices. Thus repeated application of this relation results in a color sum over $\delta$-functions, which yields the wanted color-factor.

In order to speed up the process it is also helpful to use (B.16) to reduce terms like $f^{abc} T^a$ to terms with two generators directly, instead of having four generators in an intermediate step upon rewriting $f^{abc}$ with the help of (B.18). Also

$$T^a_{ij} T^a_{ji} = \text{Tr} \langle T^a T^b \rangle = \frac{1}{2} \delta^{ab} \quad (B.19)$$

$^3$In QCD only $f^{abc}$ will enter due to the gluon self-coupling.
can be used to quickly reduce some color structures. In QCD they will occur for (potentially cut) "bubbles" of quarks, see graph (b) of Fig. B.1. Of course then some trivial relations like $\delta^{ab} T^b = T^a$ have to be built into the program as well. A nice feature of this automatic procedure is that it does not rely on "advanced" color relations like $\text{Tr} \langle T^a T^b T^c \rangle = -\delta^{bc}/(4N)$. Thus one does not have to worry about building up traces and applying rules in the correct order. In particular it is enough to write down the color structure of the occurring amplitudes. Say $M_i$ has a color structure $c_i$, then to obtain the color-factor of the squared matrix element $M_i M_i^\dagger$ one can simply use $c_i c_i^\dagger$, with the transpose of $c_i$ generated automatically, without first analyzing which traces may be formed. So obtaining the color factors with the program basically proceeds as fast as one can define the $c_i$ and enter the needed combinations into the program.

![Figure B.2: Three real NLO amplitudes occurring in hadroproduction serve as examples for the calculation of color-factors. The naming of matrix elements $M_i$ and color-structures $c_i$ is indicated. Note that in the Mathematica [57] syntax $c_i \sim c_i$ etc.](image)

For example, the color definitions entered in the Mathematica [57] program for the three sample graphs in Fig. B.2 would be simply $cI = L[c,a,b,i,j], cII = L[a,b,c,i,j]$ and $cIII = T[d,i,j] f[a,b,e] f[e,d,c]$. Here $T[d,i,j] \sim T^{ij}_{j} f[a,b,e] \sim f^{jbe}$ and the $L[a,b, \ldots, i,j]$ function automatically constructs a string of generators by inserting auxiliary "quark" indices, e.g., $L[c,a,b,i,j] \rightarrow T[c,i,k] T[a,k,l] T[b,1,j]$. The color-factor of $M_i M_i^\dagger$ is then obtained by typing $\text{su}[cI \ t[cII]]/(N^2-1)^\dagger 2$, where the function $t[c]$ generates $c^\dagger$, the function $\text{su}[c]$ calculates the color factor according to the method described above and we have divided by $(N^2-1)^2$ to average over the two incoming gluon color indices. The result is $\frac{1}{8N^2}$ if $N \geq 3$. Furthermore $\text{su}[cI \ t[cIII]]/(N^2-1)^\dagger 2$ gives $\frac{N^2}{8(N^2-1)}$ and $\text{su}[cII \ t[cIII]]/(N^2-1)^\dagger 2$ yields $\frac{N^2}{8(N^2-1)}$.

It is often advantageous to decompose the color factors into different parts in order to collect the matrix elements. We have chosen to rewrite them in terms of the Casimir operator color factors $C_F \equiv \frac{N^2-1}{2N}$ and $C_A \equiv N$. In the real gluon-gluon matrix elements, of which Fig. B.2 shows three examples, all color factors have a common factor $\frac{1}{8(N^2-1)}$ and the rest can be decomposed into linear combinations of $(2C_F)^2$, $C_F^2$ and 1. So the total result can be organized into three different color parts. On one hand this allows cancellations between different squared matrix elements to take place and on the other hand we can directly obtain results which have similar colorless amplitudes. For example the corresponding real photon-photon matrix element result can be read off as the $(2C_F)^2$.
coefficient. But one has to keep in mind that this decomposition is not unique, but rather a tool for efficiently organizing the results.

## B.4 Two Useful Slavnov-Taylor Identities

Instead of employing the most general Slavnov-Taylor identity in its functional form to derive our special result, we use the fact that the Green’s functions themselves are directly invariant under Becchi-Rouet-Stora (BRS) transformations [75], see for example [126, 50]. The BRS transformations are given by

\[
\delta_{\text{BRS}} A^a_{\mu} = \delta \omega \, T^a_{\mu \nu} \xi^\nu, \\
\delta_{\text{BRS}} \xi^a = -\frac{1}{2} g_{\nu} \, f^{abc} \xi^b \xi^c \delta \omega, \\
\delta_{\text{BRS}} \xi^{\mu a} = -\frac{1}{\alpha} \delta \omega \partial^\mu A^a_{\mu}, \\
\delta_{\text{BRS}} \Psi = i g_{\mu} \, T^a \partial^\mu \xi^a \Psi, \\
\delta_{\text{BRS}} \overline{\Psi} = i g_{\mu} \, \overline{T}^a \partial^\mu \xi^a \overline{\Psi},
\]

where \(\delta \omega\) is an infinitesimal Grassmann variable \(\delta \omega^2 = 0\), which anticommutes with the (Grassmann) ghost fields. The other notations for the fields and covariant derivatives correspond to those used in (4.2) to (4.5). We will for simplicity use the unrenormalized Lagrangian, but exactly the same derivations can be made for the renormalized Lagrangian, using the corresponding renormalized BRS transformations, see for example [64].

We consider the time-ordered four-point function \(\langle 0 | T(\overline{\Psi}(x_4) \Psi(x_3) \xi^{\mu a}(x_1) A^b_{\mu}(x_2)) | 0 \rangle\), where the fields are considered to be external and are to be used in the S-matrix. Its invariance under BRS transformations means

\[
0 \equiv \delta_{\text{BRS}} \langle 0 | T(\overline{\Psi} \Psi \xi^{\mu a} A^b_{\mu}) | 0 \rangle \\
= \langle 0 | T[\delta_{\text{BRS}} \overline{\Psi}] \Psi \xi^{\mu a} A^b_{\mu}] | 0 \rangle + \langle 0 | T[\delta_{\text{BRS}} \Psi] \xi^{\mu a} A^b_{\mu}] | 0 \rangle + \langle 0 | T[\delta_{\text{BRS}} \xi^{\mu a}] A^b_{\mu}] | 0 \rangle + \langle 0 | T[\delta_{\text{BRS}} A^b_{\mu}] | 0 \rangle.
\]

Let us examine the first term in more detail, it yields with (B.20)

\[
\langle 0 | T[\delta_{\text{BRS}} \overline{\Psi}(x_4)] \Psi(x_3) \xi^{\mu a}(x_1) A^b_{\mu}(x_2)] | 0 \rangle \\
= ig_{\mu} \delta \omega \langle 0 | T(\overline{\Psi}(x_4) T^\nu \xi^{\nu a}(x_4) \Psi(x_3) \xi^{\mu a}(x_1) A^b_{\mu}(x_2)) | 0 \rangle,
\]

Now we wish to know if this can contribute to the S-matrix. In the LSZ reduction formalism, \(\langle 0 | T(\overline{\Psi} \Psi A^b_{\mu}) | 0 \rangle\) will be multiplied by the inverse propagators of the external fields, which for \(\overline{\Psi}\) gives \(k_4 - m\), i.e., the external legs are “amputated”. Here we have considered the transformation to (external) momentum space with \(x_{1,2,3,4} \to k_{1,2,3,4}\). But from the \(\overline{\Psi}\) in the two particle state of (B.22), there will be no corresponding one particle
propagator $\sim 1/(p_4^2 - m^2)$, since only the sum of the momenta of the two particles gives $k_4$. A momentum space representation of (B.22) is shown for illustration in Fig. B.3. Then taking the on-shell limit $p_4^2 - m^2$ will give zero for the $S$-matrix contribution of (B.22), since there is no cancellation $(p_4^2 - m^2)/(p_4^2 - m^2) = 1$. The second term in (B.21) suffers the same fate when we put $\Psi$ on-shell, and in the last term the covariant derivative reduces to a partial derivative if we set $A^\mu_2$ on-shell, since again the contribution due to two fields at one point vanishes with respect to the $S$-matrix. So we can, keeping the use with the $S$-matrix in mind, write (B.21) as

$$-\frac{1}{\alpha} \delta \omega \langle 0 | T [\bar{\Psi} \gamma^\mu A^\mu_2] | 0 \rangle + \delta \omega \langle 0 | T [\bar{\Psi} \xi^{\alpha a} (\partial_\nu \xi^b_2)] | 0 \rangle = 0 . \quad (B.23)$$

Note that in the first term we now have two gluons, in the second a ghost and an antighost and that the only particle we did not have to set on-shell to proceed in our derivation was the original ghost field $\xi^{\alpha a}$.

![Diagram](image)

Figure B.3: The momentum space representation of (B.22) as it would appear in the $S$-matrix. This contribution vanishes due to the absence of a one-particle pole in $k_4$.

In Feynman gauge $\alpha = 1$ this will correspond to the condition on the amplitudes\(^4\)

$$k_1^\mu M^{ab}_{\mu \nu} = -k_2^\nu M_{\mu \nu}^{ab} , \quad (B.24)$$

where on the l.h.s. we have a sum of all relevant amplitudes for two external gluons multiplied with $k_1^\mu$, instead of a polarization vector $\varepsilon^\mu(k_1, k_1)$. On the right hand side we have a corresponding sum of amplitudes, where instead of the gluons a ghost can “run through”, i.e., since only connected diagrams contribute and one couples always a ghost-gluon-antighost, the external ghost and antighost are connected. Note that we can add an arbitrary number of external on-shell fermions without changing the derivation of (B.24). Also if the unsplit gluon on the left hand side is transverse, then as we multiply by $\varepsilon_2^\nu = \varepsilon^\nu(k_2, k_2)$ in the $S$-matrix and $\varepsilon_2 \cdot k_2 = 0$, the contribution vanishes. Hence we could also add an arbitrary number of external transverse on-shell gluons to the initial vacuum expectation value and still obtain (B.24). Obviously by exchanging positions and labels we can also derive

$$k_2^\nu M^{ab}_{\mu \nu} = -k_1^\mu M_{\mu \nu}^{ab} , \quad (B.25)$$

\(^4\)Both sides will also be multiplied by the polarization tensor $\varepsilon_2^\nu$ of the gluon in the original vacuum expectation value to obtain the $S$-matrix.
and all considerations given above apply to the other leg, respectively. If we replace both polarization tensors with the momenta and set $k_1^2 = k_2^2 = 0$, then obviously

$$k_1^\mu k_2^\nu M_{\mu\nu}^{ab} = 0 .$$  \hfill (B.26)

The results (B.24) to (B.26) are the generalization in QCD of the well known result, that in QED due to gauge invariance we get zero when replacing a polarization vector by the corresponding momentum. We can now use (B.24) to (B.26) to easily calculate

$$P^{\mu\alpha}(k_1)P^{\nu\beta}(k_2)M_{\mu\nu}^{ab}M_{\alpha\beta}^{cd} = (-g^{\mu\alpha})(-g^{\nu\beta})M_{\mu\nu}^{ab}M_{\alpha\beta}^{cd} = M_{gh}^{ab}M_{gh}^{cd} - M_{gh}^{ab}M_{gh}^{cd} ,$$  \hfill (B.27)

where $P^{\mu\alpha}(k_1)$ and $P^{\nu\beta}(k_2)$ are physical polarization tensors as defined by summing over $\lambda_1$ and $\lambda_2$, respectively, in (2.14). The arrows at the ghost amplitudes indicate the direction of the ghost line, from $k_1$ to $k_2$ or vice versa. The dependence on the arbitrary light-like $\eta$ drops out completely and we have thus proven the “external ghost trick”. The identity Fig. B.4 was derived first in [52] and later shown to survive the renormalization process in [53].

![Figure B.4: Pictorial representation of the Slavov-Taylor identity (B.24). The dotted line with a double line end represent the replacement of a polarization vector $\varepsilon^\mu_i \rightarrow k_1^\mu$, with possibly $k_1^2 \neq 0$, the spiral with line represents an on-shell gluon $k_2^2 = 0$ which is not transverse $\varepsilon_2 \cdot k_2 \neq 0$. The circle represents the set of all relevant Feynman graphs, and there can be other external lines which have to be on-shell (and for gluons transverse).]

A second useful Slavov-Taylor identity is obtained from $(0|\mathcal{T}[(\partial^\mu A_\mu^a(x))\xi^b(y)]|0)$, where this time we put no conditions on the fields. Setting its BRS transformation to zero yields

$$\frac{1}{\alpha} \langle 0 | \mathcal{T}[(\partial^\mu A_\mu^a(x)) (\partial^\nu A_\nu^b(y))] | 0 \rangle = \frac{1}{\alpha} \langle 0 | \mathcal{T}[(\partial^\mu D_\mu^a \xi^b(x)) \xi^b(y)] | 0 \rangle = 0 ,$$  \hfill (B.28)

where we have used the equation of motion for $\xi^b$ from

$$\partial^\mu \frac{\partial \mathcal{L}}{\partial (\partial_\mu \xi^a)} - \frac{\partial \mathcal{L}}{\partial \xi^a} = \partial^\mu D_\mu^a \xi^b = 0 .$$  \hfill (B.29)

The choice for gauge fixing (4.3) leads to the following regularization prescription for equal times

$$\langle 0 | \mathcal{T}[(\partial^\mu A_\mu^a(x)) (\partial^\nu A_\nu^b(y))] | 0 \rangle = \partial^\mu_2 \partial^\nu_2 \langle 0 | \mathcal{T}[A_\mu^a(x) A_\nu^b(y)] | 0 \rangle + i \delta_{ab} \delta^{(4)}(x - y) ,$$  \hfill (B.30)
see [64]. Taking the Fourier transform $x - y \rightarrow k$ of $\langle 0 | T[A^a_\mu(x) A^b_\nu(y)] | 0 \rangle$ gives the full gluon propagator $\hat{D}^{ab}_{\mu\nu}$ in momentum space, and we derive

$$i \frac{k^\mu k^\nu}{\alpha} \hat{D}^{ab}_{\mu\nu} = \delta_{ab}.$$  \hspace{1cm} (B.31)
Appendix C

Virtual Plus Soft Coefficients

First we list the polarized coefficients for the virtual plus soft $(V+S)$ photon-gluon reduced partonic cross section as defined by (7.27), i.e., sorted according to their color-factors. Furthermore, the $\ln(\Delta/m^2)$ terms are collected in separate coefficients and all the logarithms depending on the renormalization scale $\mu_r$ have been rewritten, so that the only dependence now resides in the $\ln(\mu^2_r/\mu^2_f)$ of (C.5). Note that in [35] this coefficient was written with $\ln(\mu_r/\mu_f)$. $\Delta B_{\text{QED}}$ is given by (2.21), $\beta \equiv \sqrt{1 - 4m^2/s}$, $\varkappa \equiv (1 - \beta)/(1 + \beta)$, and $t$ and $u$ are defined in (2.18).

$$\Delta L_{\text{QED}} = \left[ -t_1(t_1 + 1)/t(u_1) - u_1(t_1 + 2u_1)/(t_1 u_1) \right] / 4 + \left[ -4m^2 s(2t_1^2 - t_1 u_1 + 2u_1^2) + t_1 u_1(5t_1^2 + 2t_1 u_1 + 5u_1^2) \right] / (4t_1^2 u_1^2) + \left\{ \beta(2m^2 s + t_1^2 + 4t_1 u_1 + u_1^2) / (4t_1 u_1) + \left[ t_1^2 u_1^2 (3t_1^2 + 4t_1 u_1 + 3u_1^2) + 4m^4 (t_1^4 + 2t_1^3 u_1 - 8t_1^2 u_1^2 + 2t_1 u_1^3 + u_1^4) \right] / (4t_1^4 u_1^4) \right\} \zeta(2) - \left\{ \beta(2m^2 s + t_1^2 + 4t_1 u_1 + u_1^2) / (4t_1 u_1) + \left[ -2m^4 \left( 6m^4 + 9m^2 t_1 + 4t_1^2 \right) + 1/t_1 \left( \left( 2m^2 + t_1 \right) (8m^4 + 9m^2 t_1 + 2t_1^2) \right) u_1 + 3t \left( 2m^2 + t_1 \right) u_1^2 \right] / (4t_1^2 u_1^4) - \left[ t_1^2 u_1 (t_1 + 2u_1) + 4m^4 \left( t_1^3 + 3t_1^2 u_1 - t_1 u_1^2 - u_1^3 \right) + 2m^2 \left( t_1^4 + t_1^3 u_1 - 3t_1^2 u_1^2 + 2t_1 u_1^3 - u_1^4 \right) \right] / (2\beta s t_1^2 u_1^2) \ln \varkappa \right\} \left[ -\left( -\frac{u_1}{m^2} \right) \right] \left( \ln \left( -\frac{t_1}{m^2} \right) \right) + \left\{ -t_1 u_1^3 (3t_1 + 2u_1) + 4m^6 (3t_1^2 + 4t_1 u_1 + 3u_1^2) + m^2 u_1^2 (15t_1^2 + 13t_1 u_1 + 8u_1^2) + 2m^4 u_1 (12t_1^2 + 13t_1 u_1 + 9u_1^2) \right\] / (4t_1 u_1^2) - \left[ s_1 t_1 u_1^2 (2t_1 + u_1) - 4m^4 \left( t_1^3 + t_1^2 u_1 - 3t_1 u_1^2 - u_1^3 \right) + 2m^2 \left( t_1^4 + t_1^3 u_1 - 3t_1^2 u_1^2 + 2t_1 u_1^3 - u_1^4 \right) \right] / (2\beta s t_1^2 u_1^2) \ln \varkappa \right\} \left[ -\left( -\frac{u_1}{m^2} \right) \right] \left( \ln \left( -\frac{t_1}{m^2} \right) \right) + \left\{ (m^2 s - t_1 u_1) / (\beta t_1 u_1) + \beta(2m^2 s + t_1^2 + 4t_1 u_1 + u_1^2) / (2t_1 u_1) \ln (1 + \varkappa) \right\} \ln \varkappa + \left\{ 2m^2 \left( t_1^3 - t_1 u_1^2 + u_1^2 \right) / (2t_1 u_1 + u_1^2) - 2m^4 (t_1^2 + 2t_1 u_1 + 5u_1^2) \right\} / (2t_1^2 u_1) \cdot \text{Li}_2 \left( \frac{t}{m^2} \right) + \left\{ 2m^2 (t_1 - u_1) u_1^2 + u_1^2 \left( t_1^2 + 2t_1 u_1 + 2u_1^2 \right) - (t_1^2 + 2t_1 u_1 + 5u_1^2) \right\}$$.

\]
\[ \Delta L_{RF} = \Delta B_{QED} \ln \frac{\mu_r^2}{\mu_f^2}. \]  

(Appendix C. Virtual Plus Soft Coefficients 169)

Next we list the coefficients of the unpolarized reduced \( V + S \) partonic cross section for the quark-antiquark subprocess of hadroproduction, according to (7.49). The polarized parts follow exactly from \( \Delta K_i = -K_i \) in each case, i.e., helicity is conserved. Again the coefficients are sorted according to their color-factors, the \( \ln \Delta/m^2 \) terms are collected separately, and the logarithms depending on the renormalization scale have been brought into the form \( \ln \mu_r^2/\mu_f^2 \) and are collected in (C.11). \( A_{QED} \) is given in (2.30).

\[
K_{QED} = -4 \frac{(t_1 - u_1)}{s\beta^2} \ln \frac{s}{m^2} - 2 \frac{(t_1 - u_1)}{s} \left[ 2\zeta(2) + \ln^2 \frac{s}{m^2} \right] - 4\frac{(t_1 u_1 - 2m^2 s)}{st} \ln \left( \frac{t_1}{m^2} \right) \\
+ 4\frac{(t_1 u_1 - 2m^2 s)}{s u} \ln \left( \frac{u_1}{m^2} \right) + 4\frac{m^2}{s\beta} \ln \chi + 4\frac{(2m^2 + t_1 - u_1)}{s} \\
\cdot \ln \left( -\frac{s}{t_1} \right) - \text{Li}_2 \left( \frac{t_1}{m^2} \right) - 2\frac{(2m^2 - t_1 + u_1)}{s} \\
\cdot \ln \left( -\frac{u_1}{t_1} \right) - \text{Li}_2 \left( \frac{u_1}{m^2} \right) - 2\frac{(8m^4 - 8m^2 s + 2^2)(t_1 - u_1)}{s^3\beta^3} \\
\cdot \left[ 2\zeta(2) + \ln^2 \chi + 4\text{Li}_2(-\chi) \right] + A_{QED} \left\{ -10 + 4\zeta(2) + 3\ln \frac{s}{m^2} - 2\ln \frac{s}{m^2} \ln \frac{t_1 u_1}{m^4} \\
+ \ln^2 \frac{t_1 u_1}{m^4} + \ln \frac{\mu_f^2}{m^2} \left[ -3 + 2 \ln \frac{t_1 u_1}{m^4} \right] + \frac{1}{\beta} \ln \chi + 2\text{Li}_2 \left( 1 - \frac{m^2 s}{t_1 u_1} \right) - 8 \ln \frac{t_1}{u_1} \\
\cdot \left( \ln \frac{s}{m^2} + \ln \chi \right) - \text{Li}_2 \left( 1 - \frac{t_1}{\chi u_1} \right) + \text{Li}_2 \left( 1 - \frac{u_1}{\chi t_1} \right) \right\} \\
\cdot \left[ -6 + 8 \ln(1 - \chi) - 3\ln \chi + 4\ln(1 + \chi) + 4\text{Li}_2(\chi) + 2\text{Li}_2(\chi^2) \right] \}, \quad (C.6)
\]

\[
K_{QED}^\Delta = -4A_{QED} \ln \frac{\Delta}{m^2} \left[ 1 - \ln \frac{\Delta}{m^2} + \ln \frac{\mu_f^2}{m^2} - 4\ln \frac{t_1}{u_1} + \ln \frac{t_1 u_1}{m^2 s} - 2\frac{m^2 - s}{s\beta} \ln \chi \right], \quad (C.7)
\]

\[
K_{OK} = -\frac{8m^2}{s\beta^2} + 16m^4 + 12m^2 s - s \left[ s + 3\beta^2(u_1 - t_1) \right] \ln \frac{s}{m^2} - 2\frac{m^2 - 3t_1 + 3u_1}{2s} \\

Acknowledgements

It is a pleasure to thank Prof. Dr. E. Reya for suggesting this very interesting research topic to me. His generous support and his helpful advice have kept me on track through the years. I have benefitted continuously from his ability to spot what is important.

I am also particularly grateful to Dr. M. Stratmann for the fruitful collaboration on this project. He has generously shared his insight with me and his knowledge has guided this investigation. It is amazing how well we have worked together, in spite of communicating only by email most of the time.

My colleagues next door, Dr. S. Kretzer and I. Schienbein, have sacrificed many hours of their valuable time for physics discussions with me. The free exchange of ideas with them has been very helpful and I enjoyed it immensely. I would also like to thank the last three persons for critically reading parts of the manuscript and J. Noritzsch for some LaTeX magic that improved its looks.

Finally, I would like express my gratitude to Prof. Dr. M. Glück and all the other members of TIV for creating such an inspiring work environment. The sheer number of talented, successful and open (former) TIV members I have met speaks for itself.
